Abstract

Drought, salinity and low temperatures are major factors limiting crop productivity and quality. Sucrose non-fermenting1-related protein kinase 2 (SnRK2) plays a key role in abiotic stress signaling in plants. In this study, TaSnRK2.8, a SnRK2 member in wheat, was cloned and its functions under multi-stress conditions were characterized. Subcellular localization showed the presence of TaSnRK2.8 in the cell membrane, cytoplasm and nucleus. Expression pattern analyses in wheat revealed that TaSnRK2.8 was involved in response to PEG, NaCl and cold stresses, and possibly participates in ABA-dependent signal transduction pathways. To investigate its role under various environmental stresses, TaSnRK2.8 was transferred to Arabidopsis under control of the CaMV-35S promoter. Overexpression of TaSnRK2.8 resulted in enhanced tolerance to drought, salt and cold stresses, further confirmed by longer primary roots and various physiological characteristics, including higher relative water content, strengthened cell membrane stability, significantly lower osmotic potential, more chlorophyll content, and enhanced PSII activity. Meanwhile, TaSnRK2.8 plants had significantly lower total soluble sugar levels under normal growing conditions, suggesting that TaSnRK2.8 might be involved in carbohydrate metabolism. Moreover, the transcript levels of ABA biosynthesis (ABA1, ABA2), ABA signaling (ABI3, ABI4, ABI5), stress-responsive genes, including two ABA-dependent genes (RD20A, RD29B) and three ABA-independent genes (CBF1, CBF2, CBF3), were generally higher in TaSnRK2.8 plants than in WT/GFP controls under normal/stress conditions. Our results suggest that TaSnRK2.8 may act as a regulatory factor involved in a multiple stress response pathways.

Introduction

Plant growth and crop production are adversely affected by environmental stresses such as extreme temperatures, drought, and high salinity. As adaptable organisms, plants have developed complex signaling networks to regulate biochemical and physiological acclimation [1,2]. Many studies have indicated the involvement of stress signaling cascades composed of second messengers [3], phospholipids [4], phosphatases [5] and protein kinases [6]. However, most of the components that transduce stress signals remain to be discovered and elucidated.

One of the major pathways by which extracellular stimuli are transduced into intracellular responses is the calcium-dependent protein kinase (CDPK) signaling cascade, which is activated by ABA and other diverse stress signals [7,8]. CDPK kinases are calcium-regulated and are distinguished by a structural arrangement in which a calmodulin-like regulatory domain is located at the C-terminal end of the enzyme. The sucrose non-fermenting1 (SNF1) protein kinase family, belonging to the CDPK-SnRK superfamly [9], comprises SNF1 in yeast, AMP-activated protein kinases (AMPK) in mammals, and SNF1-related protein kinases (SnRKs) in plants. In yeast and mammals, all these kinases are involved in regulation of carbon metabolism and energy status in their respective systems, whereas in plants, they may represent interfaces between metabolic and stress signaling. Furthermore, accumulating evidence indicates that plant SnRKs may be hubs within a network of interacting signaling pathways, rather than being components of simple signaling cascades [10,11].

Plant SnRKs are grouped into three subfamilies: SnRK1, SnRK2 and SnRK3. SnRK1 kinase is well characterized at the molecular and biochemical levels, and evidence indicates that SnRK1s have a role in global regulation of carbon and nitrogen metabolism, whereas SnRK2 and SnRK3 mainly function in stress signaling [12]. In the process of plant evolution, a number of duplicated protein kinases involved in plant development may have evolved as resistance genes by selection or acquisition to address various environmental stresses [13,14]. Interestingly, recent studies have suggested that SnRK2 and SnRK3 originated by gene duplication of SnRK1, and then diverged rapidly during plant evolution to fulfill new roles that enabled plants to develop networks linking stress and ABA signaling with metabolic signaling [11]. The SnRK2 and SnRK3 gene subfamilies are unique to plants [15]. To date, most studies on SnRK2 and SnRK3 kinases focus on their involvement in response to stresses. One of best studied kinases in the SnRK3 family, SOS2, is which is required for...
Na\(^+\) and K\(^+\) homeostasis and abiotic stress tolerance is involved in responses to salt stress and ABA signaling [16,17]. Increasing evidence shows that SnRK2 genes play crucial roles in abiotic stress response, and might be involved in diverse developmental processes in plants. In Arabidopsis, ten SnRK2s have been identified, of which five members (SnRK2.2, SnRK2.3, SnRK2.6, SnRK2.7 and SnRK2.8) are activated by ABA, and all members, except SnRK2.9, could be activated by hyperosmotic and salinity stresses, whereas none was activated by cold stress [18,19]. Furthermore, overexpression of SnRK2.8 resulted in up-regulation of stress-related genes and led to enhanced drought tolerance in Arabidopsis [20]. Recently, three members SBE2/D/E/I were identified to function as main positive regulators of ABA signaling in response to water stress [21]. Similarly, 10 SnRK2s, designated SAPK7-10, were identified in rice. All were activated by hyperosmotic stress, and SAPK8-10 were also activated by ABA [22]. Overexpression of SAPK4 significantly enhanced tolerance to salt in rice [23]. Recently, ten maize SnRK2 members were cloned, and most ZmSnRK2s were induced by one or more abiotic stresses [24]. In wheat, the first SnRK2 cDNA clone, PkBA1, was isolated from an ABA-treated wheat embryo cDNA library [25]. In our recent study, the wheat TaSnRK2.4 gene, expressed strongly in booting and spikes, was induced by multi-stresses and ABA application. Overexpression of TaSnRK2.4 resulted in delayed seedling establishment, longer primary roots and enhanced tolerance to abiotic stresses in Arabidopsis [26]. Although various studies show that SnRK2s are activated rapidly in response to abiotic stresses, knowledge of TaSnRK2.8 stress resistance in wheat. In this study, we characterized muti-environmental stresses, such as drought, salinity and extreme Arabidopsis tolerance assays indicated that activated rapidly in response to abiotic stresses, knowledge of TaSnRK2.4 isolated from an ABA-treated wheat embryo cDNA library [25]. SnRK2.9 stresses [24]. In wheat, the first SnRK2 cDNA clone, was identified in rice. All were activated by hyperosmotic and salinity stresses, whereas none was activated by cold stress [18,19]. Furthermore, overexpression of SnRK2.8 resulted in up-regulation of stress-related genes and led to enhanced drought tolerance in Arabidopsis [20]. Recently, three members SBE2/D/E/I were identified to function as main positive regulators of ABA signaling in response to water stress [21]. Similarly, 10 SnRK2s, designated SAPK7-10, were identified in rice. All were activated by hyperosmotic stress, and SAPK8-10 were also activated by ABA [22]. Overexpression of SAPK4 significantly enhanced tolerance to salt in rice [23]. Recently, ten maize SnRK2 members were cloned, and most ZmSnRK2s were induced by one or more abiotic stresses [24]. In wheat, the first SnRK2 cDNA clone, PkBA1, was isolated from an ABA-treated wheat embryo cDNA library [25]. In our recent study, the wheat TaSnRK2.4 gene, expressed strongly in booting and spikes, was induced by multi-stresses and ABA application. Overexpression of TaSnRK2.4 resulted in delayed seedling establishment, longer primary roots and enhanced tolerance to abiotic stresses in Arabidopsis [26]. Although various studies show that SnRK2s are activated rapidly in response to abiotic stresses, knowledge of TaSnRK2.8 in wheat is fragmentary.

As a world staple crop, wheat production is constrained by muti-environmental stresses, such as drought, salinity and extreme temperatures. Therefore, understanding the molecular basis of abiotic stress responses is necessary for genetic improvement of stress resistance in wheat. In this study, we characterized TaSnRK2.8 in wheat and observed its expression patterns under various abiotic stresses and in different wheat tissues. Abiotic stress tolerance assays indicated that TaSnRK2.8 overexpressing in Arabidopsis significantly increased tolerance to drought, salt and cold stresses.

Materials and Methods

Plant materials, growth conditions, and stress treatments

Common wheat (\textit{Triticum aestivum} L.), genotype “Hanxuan 10” with a conspicuous drought-tolerant phenotype was used in this study. Wheat seedling growth conditions, and stress treatment assays were performed as described previously [26]. To study the expression of the target gene at different developmental stages, wheat seedling leaves and roots, spindle leaves at booting, and spikes at the heading stage were sampled. Seedlings were grown in the growth chamber, and spindle leaves at jointing and spikes were sampled from field plots without environmental stress [26].

Cloning the full-length TaSnRK2.8 cDNA and sequence analysis

Various wheat tissues were collected to extract total RNA with TRIZOL reagent (Invitrogen). Based on the candidate EST of TaSnRK2.8 from the dehydration-inducible cDNA library of wheat established in our laboratory [27], the putative full-length TaSnRK2.8 cDNA was obtained by \textit{in silico} cloning, and a pair of gene-specific primers was designed to amplify the full-length cDNA (F: 5'-GGGGAAACCGAGCCCTATCGGCAGCCG-3' (HindIII site in bold italics) and R: 5'-GAGAGTCGACAGCATACGATGCTCTCCACTG-3' (BamHI site in bold italics), then inserted into the pIT163-GFP vector. The fusion construct (TaSnRK2.8-GFP) and control (GFP) were transformed into living onion epidermal cells by particle bombardment with a GeneGun (Biorad Helios\textsuperscript{TM}), according to the instruction manual (helium pressure, 150–300 psi). After incubation on Murashige and Skoog (MS) medium (pH 5.7) solidified with 1.5% agar at 28°C for 36–48 h, the onion cells were observed with a laser scanning confocal microscope (Leica TCS-NT).

Subcellular localization of TaSnRK2.8 protein

The ORF of TaSnRK2.8 without the termination codon was amplified with primers F: 5'-GAGAGTCGACAGCATACGATGCTCTCCACTG-3' and R: 5'-GAGAGTCGACAGCATACGATGCTCTCCACTG-3' (BamHI site in bold italics), then inserted into the pIT163-GFP vector. The fusion construct (TaSnRK2.8-GFP) and control (GFP) were transformed into living onion epidermal cells by particle bombardment with a GeneGun (Biorad Helios\textsuperscript{TM}), according to the instruction manual (helium pressure, 150–300 psi). After incubation on Murashige and Skoog (MS) medium (pH 5.7) solidified with 1.5% agar at 28°C for 36–48 h, the onion cells were observed with a laser scanning confocal microscope (Leica TCS-NT).

Expression patterns of TaSnRK2.8 in wheat

Quantitative real-time PCR (qRT-PCR) were used to determine the expression patterns of TaSnRK2.8. The \textit{Tubulin} transcript was used as an internal control to quantify the relative transcript levels. The qRT-PCR were performed in triplicate with an ABI PRISM\textsuperscript{TM} 7000 system using the SYBR Green PCR master mix kit (Applied Biosystems). Specific primers (F: 5'-CGGGAGAGAGAGAGATGGCAGGACGATGACT-3', R: 5'-CTCAGAAGGCTCACCACCACTG-3') were designed according to the cDNA sequence. The relative level of gene expression was determined using the 2\(^{-}\Delta \Delta Ct\) method [28]. \(\Delta \Delta Ct = (C_{T,\,\text{Target}} - C_{T,\,\text{Tubulin}})_{\text{Time} \, x} - (C_{T,\,\text{Target}} - C_{T,\,\text{Tubulin}})_{\text{Time} \, 0}\). The Ct (cycle threshold) values for both the target and internal control genes were the means of the triplicate independent PCRs. Time \(x\) is any treatment time point (1, 3, 6, 12, 24, 48 or 72 h) and time 0 represents the untreated time (0 h).

Leaves, roots, stems, and spikes were sampled to detect the transcription level of TaSnRK2.8 in different wheat tissues. The expression of TaSnRK2.8 in seedling leaves was regarded as standard because of its lowest expression level in that tissue, and the corresponding formula was modified as \(\Delta \Delta Dt = (C_{T,\,\text{Target}} - C_{T,\,\text{Tubulin}})_{\text{DST}} - (C_{T,\,\text{Target}} - C_{T,\,\text{Tubulin}})_{\text{ST}}\). DST refers to the developmental stage tissue. In addition, to identify the relative expression of TaSnRK2.8 in transgenic Arabidopsis, the \textit{Actin} transcript of Arabidopsis was used to quantify the expression levels, and the lowest expression level among transgenic lines was regarded as standard.

Transgenic plant generation

\textit{TaSnRK2.8} cDNA containing the entire ORF was cloned into the \textit{Kpn} I and \textit{Sal} I sites of pZPP211 [29] as a GFP-lased fragment under control of the CaMV 35S promoter and NOS terminator, using primers 5'-GAGAGTTACGACGCTATCGGCCGCCG-CG-3' (\textit{Kpn} I site in bold italics) and 5'-GAGAGTCGCACAGCATACCGCATGCACAGGACCGGCG-CG-3' (\textit{Sal} I site in bold italics). The p55S-TaSnRK2.8-GFP-NOS vector was each introduced into wild type \textit{Arabidopsis} (Columbia ecotype) plants by floral infiltration. Positive transgenic plants were identified in silico cloning, and a pair of gene-specific primers was designed to amplify the full-length cDNA (F: 5'-GGGGAAACCGAGCCCTATCGGCAGCCG-3', R: 5'-GAGAGTCGACAGCATACGATGCTCTCCACTG-3').

Database searches were performed through NCBI/GenBank/Blast. Sequence alignments and comparisons were performed using the MegAlign program in DNAStar. Protein predictions were performed using the Expasy program in http://expasy.hcuge.ch/prosite.html and SignalP (http://genome.cbs.dtu.dk/services/SignalP). GFP::IAP and GPP::IAP were used to construct a phylogenetic tree of TaSnRK2.8, TaSnRK2.4, PKABA1 and SnRK2 members from other plant species.
Morphological characterization of transgenic Arabidopsis

Arabidopsis seeds were sterilized for 10 min in 10% (v/v) sodium hypochlorite solution containing 0.02% (v/v) Triton X-100, rinsed with sterilized water several times, and then sown on MS medium solidified with 0.8% agar. Seeds were vernalized overnight at 4°C before transferred to a growth chamber (22°C, 70% humidity, 150 μM m⁻² s⁻¹, 12 h light/12 h dark cycle). To examine the root morphology, 3-day-old seedlings were grown on MS medium solidified with 1.0% agar, and the plates were placed vertically so that the root tips pointed downwards. To characterize seedling size and seed production of TaSnRK2.8 Arabidopsis, 7-day-old seedlings were planted in soil and cultured in a growth chamber.

Total soluble sugar analyses

Total soluble sugars were determined as fructose equivalents using the anthrone colorimetric assay [30] at 620 nm with a spectrophotometer (LG-721, BioRad). After detachment from roots, four-week-old plants were put into liquid nitrogen immediately and dehydrated in a refrigerated-vacuum evaporator at 8.1 kPa air pressure and −60°C for 24 h. After dehydration, samples were dried at 80°C until a constant dry weight. Extractions were performed with 0.1 g dry material for each sample with three replications. Samples were boiled in 4 ml ddH₂O for 4 min. After filtration the extracted filtrates were each sample with three replications. Samples were boiled in 4 ml ddH₂O for 4 min. After filtration the extracted filtrates were transferred to volumetric flasks (5 ml) and brought to 5 ml by addition of ddH₂O.

Physiological assays

For osmotic potential (OP) analysis, 10 similar sized 4-week-old plants in each line were collected as a sample. OP was measured with a Micro-Osmometer (Fiske® Model 210, Fiske® Associates).

Free proline was extracted and quantified from fresh leaves of well-watered seedlings (0.5 g) according to the ninhydrin-based colorimetric assay [31].

Plant cell membrane stability (CMS) was determined with a conductance meter (DDS-1, YSI), CMS (%) = (initial electrical conductivity/electrical conductivity after boiling) × 100. Ten 7-day-old seedlings (grown on 1x MS medium, 0.8% agar) were placed on filter papers saturated with NaCl (300 mM) solution. When signs of stress began to appear on WT plants, seedlings were removed and immediately thoroughly rinsed with double distilled water (ddH₂O) before immersion in 20 mL ddH₂O at room temperature. After 2 h initial conductivity values of the solutions were recorded. The samples were then boiled for 30 min, cooled to room temperature, and the final conductivities were measured.

Leaf chlorophyll content (SPAD value) was measured using a Minolta Chlorophyll Meter (SPAD-502) according to the Instruction Manual. SPAD values provide an indication of the relative amounts of total chlorophyll present in plant leaves, the arbitrary SPAD value can be translated to an actual value of total chlorophyll per unit area (mg/cm²) using the equation: chlorophyll content = SPAD value ×0.003–0.048 [32]. Ten 4-week-old plants of each line with similar size were selected to measure chlorophyll content.

Chlorophyll fluorescence was measured with a portable photosynthesis system (LI-COR LI-6400 XTR), and the maximum efficiencies of PSII photochemistry, Fv/Fm = (Fm-F0)/Fm, were used to assess changes in the primary photochemical reactions of the photosynthetic potential. Ten similar sized 4-week-old plants from each line were selected to determine chlorophyll fluorescence parameters. After a three-week water-withholding period, the plants were well irrigated with NaCl solution (300 mM). Chlorophyll fluorescence was measured before stress and 12, 24, and 36 h after stress.

Stomatal conductances were measured before stress and 12, 24 and 36 h after stress with a steady state diffusion leaf porometer (Model SC-1, Decagon). Similar sized mature rosette leaves were selected for stomatal conductance determinations and the area around the merging point of the leaf transverse midline and vein was chosen as the measuring region.

Abiotic stress tolerance assays

WT and transgenic seeds were germinated on MS medium solidified with 0.8% agar. Seven-day-old seedlings, were planted on a sieve-like plate containing mixed soil (vermiculite:hu-mus = 1:1) and cultured normally in the greenhouse. The plants were exposed to various stresses at designated time points. For drought tolerance assays, seedlings were cultured in a greenhouse (22°C, 70% humidity, 150 μM m⁻² s⁻¹, 12 h light/12 h dark cycle) without watering until phenotype differences were evident between transgenic plants and controls, and then re-watered. For salt stress assays, Arabidopsis seedlings were cultured as described above. Water was withheld and then plants were well irrigated with NaCl solution (300 mM) applied from the bottom of the plate. For cold stress, plants were transferred to a 4°C growth chamber after culturing under normal conditions for three days. Further freezing tolerance assays were carried out on seedlings. Normally cultured Arabidopsis seedlings (4-week-old) were stressed in a −2°C, −6°C and −10°C freezer for 2 h, and subsequently cultured under normal growing conditions. Survival rates were scored after one week. All abiotic stresses tolerance experiments were triplicated.

Gene expression analysis

10-day-old Arabidopsis seedlings grown on MS medium were treated, or not treated, with NaCl solution (200 mM). The seedlings were harvested 3 h after stress. Real-time RT-PCR was performed as described above, and the Actin gene was used as an internal control to normalize all data. The oligonucleotide primers, used for evaluating the transcript levels of ABA1, ABA2, ABA1, ABA2, ABI1, ABI2, ABI3, ABH4, ABI5, RD20A, RD29B, CBF1, CBF2, CBF3, COR15A, in the real-time RT-PCR experiments, were applied as Ding et al. [33].

Results

Isolation and sequence analysis of TaSnRK2.8

The TaSnRK2.8 cDNA was 1431 bp in length, consisting of a 99 bp of 5’ untranslated region, a 1101 bp open reading frame (ORF), and a 235 bp 3’ untranslated region. The ORF encodes 366 deduced amino acid residues (AAR) with a calculated molecular mass of 42 kDa and a predicted pI of 4.87. Using a BLASTN search of the NCBI database, the deduced amino acid sequence showed homology with counterpart SnRK2 family members from other plant species, viz. Oriza sativa, Zea mays and Arabidopsis thaliana (Figure 1). TaSnRK2.8 has 94.8% identity to
OsSAPK8, 94% to ZmSAPK8, and 76.5% to AtSnRK2.2, respectively. Scansite analysis indicated that TaSnRK2.8 has potential serine/threonine protein kinase activities, and like other SnRK2 family members, TaSnRK2.8 showed a two domain structure, characterized by an N-terminal catalytic domain close to the SNF1/AMP kinase region and a regulatory C-terminus region in which a stretch of acidic amino acids forms a negatively charged domain. The N-terminal catalytic domain (20–204 AAR) is highly conserved, containing an ATP binding site (34–57 AAR) and a protein kinase activating signature (143–155 AAR). Additionally, in the catalytic domain one potential N-myristoylation site MYRISTYL (134–139 AAR) and one potential transmembrane spanning region (207–224 AAR) were found. The relatively short C-terminal domain is abundant in Asp (D), and is predicted to be a coiled-coil. Compelling evidence indicated that the C-terminal domain might have a role in activation of the kinase [34–36], and function in protein-protein interactions mainly involved in ABA responsiveness, and possibly involved in ABA signal transmission [22].

**Phylogenetic analysis**

A phylogenetic tree was constructed with the putative amino acid sequences of TaSnRK2.4, TaSnRK2.8 and all members of the rice, maize and *Arabidopsis* SnRK2 family. As shown in Figure 2, all of the SnRK2 genes could be divided into three distinct groups, consistent with previous reports [10,22]. TaSnRK2.8 and its counterparts, OsSAPK8, ZmSAPK8 and AtSnRK2.2, were clustered in the same clade, subclass III, whereas PKABA1 and TaSnRK2.4 belong to subclass I and subclass II, respectively.

**Subcellular localization of the TaSnRK2.8 protein**

The deduced amino acid sequence contains a putative N-myristylation site and a transmembrane region, suggesting that TaSnRK2.8 might interact with the cell-membrane and nuclear system. We used onion epidermis to determine subcellular localizations of TaSnRK2.8 in living cells. The fusion construct (TaSnRK2.8::GFP) driven by the CaMV 35S promoter was transiently expressed in living onion epidermal cells. As predicted, TaSnRK2.8-GFP was present in the cell membrane, cytoplasm and nucleus (Figure 3).

**Expression patterns of TaSnRK2.8 in wheat**

Quantitative real-time PCR were used to analyze the expression patterns of TaSnRK2.8. As shown in Figure 4A, TaSnRK2.8 was constitutively expressed in wheat, strongly in roots, weakly in stems, and marginally in leaves and spikes. Various up-regulated expression patterns occurred under diverse abiotic stresses (Figure 4B). For ABA treatment, the expression level of TaSnRK2.8 increased gradually and reached its maximum after 72 h. Under NaCl stress, TaSnRK2.8 peaked at 48 h, and then decreased. Under PEG stress, the transcription level increased rapidly, peaked at 1 h, and then declined sharply to a lower level. Under cold stress, expression increased gradually for 6 h, declined at 12 and 24 h, and reached a maximum peak at 48 h before declining again at 72 h.

---

**Figure 1. Alignment of the predicted amino acid sequences of TaSnRK2.8 and closely related SnRK2s from other plant species.** The conserved prosite motifs are underlined. Regions 1–4 represent the ATP binding site, N-myristoylation site, protein kinase activating signature and transmembrane spanning region, respectively. Alignments were performed using the Megalign program of DNAStar. Common identical amino acid residues are shown in black background. Dashed lines represent gaps introduced to maximize alignment. Abbreviations on the left side of each sequence: Os, *O. sativa*; At, *A. thaliana*; Zm, *Z. mays*. doi:10.1371/journal.pone.0016041.g001
Figure 2. Phylogenetic tree of TaSnRK2.8 and SnRK2s from other plant species. The phylogenetic tree was constructed using the putative amino acid sequences. Three distinct isoform groups are presented in grey. The phylogenetic tree was constructed with the PHYLIP 3.68 package; Bootstrap values are in percentages. doi:10.1371/journal.pone.0016041.g002

Figure 3. Subcellular localization of TaSnRK2.8 in onion epidermal cells. Cells were bombarded with constructs carrying GFP or TaSnRK2.8-GFP as described in materials and methods. GFP and TaSnRK2.8-GFP fusion proteins were transiently expressed under control of the CaMV 35S promoter in onion epidermal cells and observed with a laser scanning confocal microscope. Images were taken in dark field for green fluorescence (1, 4). The cell outline (2, 5) and the combination (3, 6) were photographed in bright field. Scale bar = 100 μm. Each construct was bombarded into at least 30 onion epidermal cells. doi:10.1371/journal.pone.0016041.g003
Identification of transgenic plants

Transgenic plants were firstly screened on kanamycin plates, and then re-confirmed by detection of GFP fluorescence and RT-PCR (Figure S1). Six transgenic lines were randomly selected to detect gene expression levels. The expression levels of TaSnRK2.8 in different transgenic lines varied significantly (Figure S1).

Overexpression of TaSnRK2.8 confers enhanced seedling growth

To evaluate the effect of TaSnRK2.8 in transgenic breeding for abiotic stress tolerance, phenotypes of TaSnRK2.8 plants were characterized at different developmental stages. Morphological assays indicated no differences in seed germination rate and seed production between transgenic and WT plants (Figure S2). However, the primary roots of TaSnRK2.8 plants were significantly longer than those of the two controls (P<0.01) (Figure 5). In addition, the seedlings of TaSnRK2.8 plants were slightly bigger than the controls, but the differences did not reach significant levels (P>0.05), and disappeared within two weeks of culture on MS medium (data not shown). These results were consistent with the function of SnRK2.8 in Arabidopsis [37], suggesting that TaSnRK2.8 might be involved in regulation of shoot and root growth.

TaSnRK2.8 might function in carbohydrate metabolism

To investigate the role of TaSnRK2.8 in carbohydrate metabolism, the total soluble sugars of TaSnRK2.8 plants were measured. The total soluble carbohydrate of transgenic lines were significantly lower than the WT and GFP controls under well-
Physiological characterization of transgenic plants

Physiological traits related to plant stress tolerance, including WRA, OP, free proline, CMS, chlorophyll content and chlorophyll fluorescence were analysed. Compared to WT and GFP plants, the six transgenic lines showed higher WRA than the two controls (P<0.05, P<0.01) (Figure 7A). TaSnRK2.8 plants had significantly lower OP than WT and GFP plants (P<0.01) (Figure 7B). Free proline is an osmoprotecting molecule, which accumulates in response to water stress and salinity [38]. In the present study, there was no difference in free proline content between WT and transgenic plants (data not shown). Therefore, free proline might not be the reason of the decreased OP.

To identify the cell membrane stability of TaSnRK2.8 plants under stress, 7-day-old seedlings were treated with NaCl (300 mM) solution on filter paper. After 5 h, WT and GFP plants began to wilt, but no signs of stress were evident on TaSnRK2.8 plants (data not shown). CMS levels in transgenic lines were significantly higher than in the two controls (P<0.01), strongly indicating that over-expression of TaSnRK2.8 increased CMS of Arabidopsis under salt stress (Figure 7C).

Under normal conditions, leaves of TaSnRK2.8 plants were slightly more green than WT and GFP plants (data not shown), and TaSnRK2.8 plants had significantly higher chlorophyll contents than the controls (P<0.01) (Figure 7D). Additionally, photochemical efficiency of PSII (Fv/Fm) determinations showed that chlorophyll florescence was slightly higher in TaSnRK2.8 plants than in controls under normal conditions, but the difference was not significant (P>0.05) (Figure 7E). Under salt stress, the chlorophyll florescence decreased by approximately 10% in TaSnRK2.8 plants and 23% in the two controls at 12 h. With additional time, the Fv/Fm for the control plants decreased much faster than in TaSnRK2.8 plants (Figure 7E). These results clearly showed that TaSnRK2.8 plants had a more robust photosynthetic potential.

Overexpression of TaSnRK2.8 results in enhanced drought, salt and cold tolerances

To examine the roles of TaSnRK2.8 in plant stress responses, TaSnRK2.8 lines and control plants were exposed to various abiotic stresses. After a two-week-water- withholding treatment, the rosette leaves of WT and GFP controls wilted severely and most became darker and died. By comparison, only some of the TaSnRK2.8 plants were slightly wilted. After re-watering for one week, all the control plants were dead, whereas 10–80% of TaSnRK2.8 plants had survived (Figure 8A). One week after salinity treatment, almost all control plants had died, whereas TaSnRK2.8 plants were still green, clear evidence that the transgenic plants were much more tolerant than the controls (Figure 8B). For cold stress analysis, the plants were cultured at 4°C. Three weeks later, differences in seedling size became evident, and TaSnRK2.8 plants were larger than the controls (Figure 8C). Further freezing tolerance assays showed that survival rates of TaSnRK2.8 plants under −2°C, −6°C and −10°C were significantly more than the controls (Figure 8D), suggesting that TaSnRK2.8 plants have increased tolerance to freezing stress. These results indicated that overexpression of TaSnRK2.8 conferred enhanced tolerance to drought, salt and cold stresses in Arabidopsis.

Expression pattern of stress-responsive genes in TaSnRK2.8 plants

Expression pattern analyses in wheat revealed that TaSnRK2.8 was involved in response to PEG, NaCl and cold stresses and ABA application. To elucidate the molecular mechanism of TaSnRK2.8 in stress response, the expression levels of the genes functioning in ABA biosynthesis and signaling or those involved in stress protection were investigated in TaSnRK2.8 plants. As expected, under normal conditions, the expressions of ABA1, ABA2, ABA3, ABI4, ABI5, CBF1, CBF2, CBF3, RD20A, RD29B were found to be consistently and significantly higher in TaSnRK2.8 plants than in WT/GFP plants, whereas there was no significant induction of expression of ABI1, ABI2, COR15A in both TaSnRK2.8 and WT/GFP plants (Fig. 9). Under salt stress, there was the same trend (data not shown).

Discussion

In this study, a dehydration-inducible cDNA library of wheat was screened for transcripts that might be significantly up-regulated under PEG stress. The identified protein kinase gene, designated as TaSnRK2.8, was cloned and characterized. The deduced amino acid sequence shows high homology with counterpart SnRK2 family members from rice, maize and Arabidopsis, implying the occurrence of SnRK2.8 before separation of monocots and dicots. Furthermore, phylogenetic tree analysis revealed that TaSnRK2.8 is a typical subclass III SnRK2 subfamily member.

N-terminal myristoylation and transmembrane spanning regions are essential for proteins to function in mediating membrane targeting and signal transduction in plant responses to environmental stress [39,40]. In the catalytic domain of TaSnRK2.8, one potential N-myristoylation site and one potential transmembrane spanning region were identified, strongly suggesting that TaSnRK2.8 may interact with the cell-membrane system when responding to stress. In yeast, SNF1 kinase was localized to the nucleus, vacuole, and cytoplasm [41], and was involved in signal transduction pathways by interacting with RNA polymerase II holoenzyme to activate transcription of glucose-responsive genes [42]. In the present study, the presence of TaSnRK2.8 in the cell membrane, cytoplasm and nucleus suggested that TaSnRK2.8 might have different functions in wheat. The results were confirmed through observing TaSnRK2.8-GFP- Arabidopsis (Figure S1), and detailed location and the signal transduction pathway of TaSnRK2.8 in stressed plants remain to be determined.
Numerous studies demonstrate that SnRK2.8 genes are involved in response to multi-environmental stresses [20,24,43]. In this study, TaSnRK2.8 was induced not only by NaCl, PEG and cold, but also by ABA (Figure 4B), suggesting that TaSnRK2.8 was involved in an intricate network for multi-environmental stress responses. Comparing these expression patterns, induction of TaSnRK2.8 by PEG was more rapid than induction by ABA. This could suggest that factors other than ABA might also involve in TaSnRK2.8 induction, and/or that ABA does not induce TaSnRK2.8 directly. In addition, the response of TaSnRK2.8 under water deficit stress is much faster than to NaCl, cold and ABA treatment. These differences also occurred at the expression level, suggesting that TaSnRK2.8 is more sensitive to drought stress.

To assess the feasibility of using TaSnRK2.8 in transgenic breeding, phenotypic traits of TaSnRK2.8 plants were closely monitored throughout the entire growth cycle (Figure S2). The results clearly demonstrated that TaSnRK2.8-overexpression does not retard plant growth, whereas it improved the root growth of transgenic plants (Figure 5A), which could benefit the uptake of water and nutrients under osmotic stress conditions.

Mammalian AMPK and yeast SNF1 act as energy-level sensors that function to regulate metabolism during low-energy conditions [44,45]. Compelling evidence indicates that plant SnRK1 and SnRK3 proteins have roles in regulating energy metabolism and stress signal transduction [11,46]. Until now, there has limit reports of SnRK2 function in carbohydrate metabolism. Recently, SnRK2.6 protein, clustered with TaSnRK2.8 in the same clade, subclass III (Figure 2), was found to mediate the regulation of sucrose metabolism and plant growth in Arabidopsis [47]. In the present study, overexpression of TaSnRK2.8 led to significantly decreased total soluble sugar content in Arabidopsis (Figure 6), suggesting that TaSnRK2.8 might function in carbohydrate metabolism. In further research, more effort should be given to deciphering the signals and molecular mechanisms of TaSnRK2.8 in carbohydrate metabolism, especially in regard to crucial downstream substrates.

Physiological indices, including WRA, CMS, OP and free proline, are typical physiological parameters for evaluating abiotic stress tolerance and resistance in crop plants. To maintain a stable intracellular environment in the presence of external environmental stresses, many plants decrease their cellular osmotic potentials through accumulation of intracellular organic osmolytes such as proline, total soluble sugar contents, glycine betaine and mannitol [48–50]. In our study, TaSnRK2.8 plants had significantly lower OP than controls (Figure 7B), but the free proline was not significantly increased, suggesting that free proline might not account for osmolyte augmentation. In addition, TaSnRK2.8 plants had significantly lower total soluble sugar contents than controls under well-watered conditions (Figure 5), but the difference vanished very soon after exposure to salt stress (data not shown). Therefore, total soluble sugar content was also not a cause of osmolyte augmentation. The results of WRA and CMS determinations were consistent with the OP results, and suggest that the enhanced multi-stress tolerance might be due to osmolyte augmentation. Thus, other types of osmolytes might be attributed to the enhanced OP in TaSnRK2.8 plants.

Figure 7. Physiological characterizations of TaSnRK2.8 plants. (A) Comparison of WRA of detached rosettes of TaSnRK2.8 plants and WT and GFP controls. (B) TaSnRK2.8 plants had lower OP than controls cultured under well-watered conditions. (C) Comparison of CMS of TaSnRK2.8 plants and controls after salinity treatment for 5 h. (D) TaSnRK2.8 plants had significantly more chlorophyll content than controls. (E) Changes in variable to maximum fluorescence ratios (Fv/Fm) in TaSnRK2.8 plants and WT and GFP controls upon high salt stress. L1–L6, six individual TaSnRK2.8 transgenic lines; WT, wild type; GFP, GFP plants. Values are mean ± SE, n = 10. * indicates significant difference between TaSnRK2.8 plants and WT control with F-test (* P < 0.05, ** P < 0.01).

A Wheat Gene TaSnRK2.8 Involved in Stress Response
Chlorophyll fluorescence from intact leaves, especially fluorescence induction patterns, is a reliable, non-invasive method for monitoring photosynthetic events and reflects the physiological status of plants [51]. The maximum efficiency of PSII photochemistry, measured as Fv/Fm, is an direct reflection of the PSII activity, and environmental stresses are associated with decreased Fv/Fm ratio [52]. In this study, we observed smaller decreases in Fv/Fm ratios in TaSnRK2.8 plants under salt stress (Figure 7E), and witnessed significantly higher chlorophyll contents in transformants. Thus TaSnRK2.8 plants might have more robust photosynthetic capabilities than non-transformed controls.

Based on the phenotypic and physiological characteristics of TaSnRK2.8 plants, we speculate that the enhanced multi-stress tolerance is possibly due to an improved root system, increased capability of osmotic adjustment, and robust photosynthetic capabilities. Under osmotic stress, longer roots might facilitate

**Figure 8. TaSnRK2.8 plants shows improved stress tolerance.** (A) TaSnRK2.8 plants and controls grown under drought stress. After planting in soil, seedlings were withheld from water for two weeks, and then re-watered for one week. (B) TaSnRK2.8 plants and controls under salt stress. Two-week-old seedlings were treated with 300 mM NaCl. (C) TaSnRK2.8 plants and controls cultured at 4°C. (D) Survival rates (%) under freezing conditions were determined as the number of visibly green plants after rehydration. Values are mean ± SE, n = 10. * indicates significant difference between TaSnRK2.8 plants and WT control with F-test (* P<0.05, ** P<0.01). doi:10.1371/journal.pone.0016041.g008
Figure 9. Comparisons of the relative transcript levels of ABA1, ABA2, ABI3, ABI4, ABI5, RD20A, RD29B, CBF1, CBF2 and CBF3 in TaSnRK2.8 plants and WT/GFP control under normal conditions. Actin was used as an internal control. The vertical column indicates the relative transcript level. Data represent means ±SD of three replicates.

TaSnRK2.8 plants to absorb more water. Robust photosynthetic capability might help transgenic plants to become more vigorous, and increased osmolytes might be helpful in reducing water loss and maintaining a higher WRA in plant cells, thus leading to enhanced water retention ability, benefiting the maintenance of regular cell turgor and avoiding damage to cell membranes, consequently enhancing drought tolerance. Under cold stress, lower OP commonly means more solutes in the plant sap, resulting in lower freezing points and hence reduced cold damage.

Under abiotic stresses, ABA is often recruited as the primary signal for increasing the transcription levels of the stress responsive genes. The function of ABA1, ABA2 and ABA3 genes in ABA biosynthesis has been well established [53,54], and the most intensively investigated regulators of ABA signaling include several ABI genes, of which ABI1 and ABI2 are negative regulators, and ABI3, ABI4 and ABI5 regulate ABA responses positively [55–58]. In the present study, the expressions of ABA1, ABA2, and ABA positive regulators (ABI3, ABI4 and ABI5) in TaSnRK2.8 plants were substantially increased compared to WT plants. Therefore, it was indicated that the enhanced stress tolerance conferred by TaSnRK2.8 overexpression may be attributed to increased ABA biosynthesis and signaling, which result in greater expression of several stress responsive genes. Moreover, it is well known that CBF genes are mainly involved in ABA independent regulation of stress responsive genes [59]. Here, the transcript levels of CBF1, CBF2 and CBF3 were also significantly higher in TaSnRK2.8 plants than the controls, suggesting that there may be ABA independent stress signaling pathways involved in TaSnRK2.8-mediated stress tolerance. Meanwhile, the high transcript levels of stress responsive genes in TaSnRK2.8 plants suggest that TaSnRK2.8 may act upstream of these genes in stress tolerance and is therefore involved in a crosstalk between ABA-dependent and ABA-independent signaling networks.

Supporting Information
Figure S1 Identification of the TaSnRK2.8 transformed Arabidopsis plants. (A) Determination of green fluorescence in roots of transgenic Arabidopsis plants. Assays were performed at the seedling stage with a laser-scanning confocal microscope. The images were taken in dark field for green fluorescence, and the root outline and combination are in bright field. (B) RT-PCR analysis of transgenic plants. M: 200-bp ladder; Lane 1, p35S-TaSnRK2.8-GFP-NOS plasmid DNA (positive control); Lane 2, wild-type Arabidopsis (negative control); Lanes 3–19, p35S-TaSnRK2.8-GFP-NOS transformed plants. (C) Expression levels of TaSnRK2.8 in transgenic Arabidopsis lines L1–L6. The lowest expression of TaSnRK2.8 in L1 was regarded as standard. (TIF)

Figure S2 Morphological characterization of TaSnRK2.8 plants. (A) Comparison of seed germination and seedlings between TaSnRK2.8 transformants and controls grown on MS medium. (B) Phenotypes of mature transgenic lines and WT grown in soil for four weeks. (C) Grain yields of TaSnRK2.8 and WT plants. The seeds of transgenic TaSnRK2.8 and WT plants cultured under well-watered conditions were harvested separately. The grain yield of each plant was measured after dehydration, and there was no significant difference. L1–L6, six individual TaSnRK2.8 transgenic lines; WT, wild type; GFP, GFP transgenic line. Values are mean ± SE, n = 10. (TIF)

Acknowledgments
The authors thank Prof. Zhensheng Li (Institute of Genetics and Developmental Biology, Chinese Academy of Sciences, Beijing) for providing the pJIT163-GFP expression vector. We thank Robert A. McIntosh (Plant Breeding Institute, University of Sydney, NSW, Australia) for critical reading of, and comments on, the manuscript.

Author Contributions
Conceived and designed the experiments: RJ. Performed the experiments: HZ. Analyzed the data: HZ. Contributed reagents/materials/analysis tools: XM CW. Wrote the paper: HZ.
