SALIVARY ALPHA-AMYLASE AS A MEASURE OF ANXIETY BEFORE AND AFTER DENTAL TREATMENT FOR VISUALLY AND HEARING-IMPAIRED CHILDREN AND THEIR MOTHERS
ABSTRACT

Objective: To assess the relationship between serum osteocalcin and periodontal clinical attachment loss (CAL) in postmenopausal women in relation to their osteoporosis risk status.

Methods: A cross-sectional study was carried out on 71 postmenopausal women in Kenari District, Central Jakarta, Indonesia. The periodontal examination for all the subjects included a CAL measurement. The serum osteocalcin level was analyzed using ELISA.

Results: The correlation between the serum osteocalcin level in patients with CAL and the risk of osteoporosis was analyzed with the Spearman test. The normal group had 29 subjects (40.84%), the osteopenic group had 23 subjects (32.39%), and the osteoporotic group had 19 subjects (26.76%). There was a significant correlation between CAL and the osteoporosis high-risk status (p<0.05) and no significant correlation between the serum osteocalcin level and the osteoporosis status (p>0.05).

Conclusion: No correlation was found between CAL and the serum osteocalcin level (p>0.05).

Keywords: Osteoporosis, Osteocalcin, Clinical attachment loss, Postmenopausal women.

INTRODUCTION

Osteoporosis is defined as a bone disease characterized by a decrease in bone mass and alterations in microarchitecture that result in bone fragility and an increased risk of fractures in the future [1]. Osteoporosis results from an imbalance between the rates of bone formation and resorption, which leads to the loss of bone mineral mass [2]. Based on data from the international osteoporosis foundation in 2013, the prevalence of osteoporosis in Indonesian women aged 50–80 years old is 23% and in those aged 70–80 years old is 53%. By 2050, one-third of the total population will be at high risk for osteoporosis [3].

Periodontitis is a destructive inflammatory disease of the tooth-supporting structures and is a major cause of tooth loss. Its presence is determined by the measurement of clinical attachment loss (CAL) [4]. The etiology of this disease is periodontal pathogens found in dental plaque that results in the inflammation of the tooth-supporting structure [2]. Periodontal diseases are correlated with several systemic diseases such as cardiovascular diseases, diabetes mellitus, osteoporosis, respiratory diseases, and others [5].

Both osteoporosis and periodontitis are bone-destructing diseases. They are characterized by increased bone resorption, host dependence, a multifactorial etiology, and stimulated by cytokine activity [4]. The relationship between osteoporosis and periodontal diseases is one of the bidirectional interferences. The reduction in bone mineral density in osteoporosis alters the trabecular pattern and may lead to a more rapid jawbone resorption caused by periodontal disease, due to the invasion of periodontal pathogenic bacteria. Conversely, the invasion of periodontal pathogenic bacteria may alter the normal homeostasis of the alveolar bone, increasing the osteoclastic activity and reducing the local and systemic bone density [6]. Pepelasi et al. [7] suggested that postmenopausal women with osteoporosis had greater gingival inflammation, periodontal attachment loss, and gingival recession than postmenopausal women with a normal bone mineral density (BMD). The American Academy of Periodontology suggested that osteoporosis is not an etiology for periodontal disease but that it can exaggerate alveolar bone destruction [8]. Postmenopausal women with a reduced BMD have a greater tendency for alveolar bone loss and CAL because inflammatory mediators are increased in the systemic and oral bones [9]. Bone turnover can be assessed by measurements of a protein produced by osteoblasts and osteoclasts: Osteocalcin, also known as the bone Gla protein, which is a noncollagenous bone protein [10].

Noncollagenous bone matrix proteins play a key role in matrix mineralization, cellular adhesion, and the regulation of cell activity during the coupling of bone formation and resorption. Osteocalcin, one of the most abundant of these proteins, plays a key role in mineralization, may act as a chemoattractant, and may be essential for osteoclast differentiation [11]. It is synthesized mainly by osteoblasts as well as a small number of odontoblasts and chondroblasts. After being synthesized, it is stored in the bone mineral matrix as hydroxyapatite crystals and is recognized as a marker of bone formation [10]. Serum osteocalcin is known to be a valid biomarker for detecting a low BMD [12].

Increases in serum osteocalcin levels are associated with rapid bone loss. In osteoporosis, there is a deficiency of the calcium level and since osteocalcin is known as a calcium-dependent biomarker and has a strong affinity with hydroxyapatite responsible for bone mineralization, Osteoporosis leads to decreased hydroxyapatite crystal formation, and hence, results in an increase in serum osteocalcin levels [13].

To the best of our knowledge, there have been no studies analyzing the association between serum osteocalcin and periodontal status in...
postmenopausal women with osteoporosis in Indonesia. The objective of this study was to assess the relationship of serum osteocalcin and periodontal CAL levels with the risk of osteoporosis in postmenopausal women.

METHODS
A cross-sectional study was carried out in 71 postmenopausal women ranging in age from 48 to 87 years in the Kenari District, Central Jakarta, Indonesia. The inclusion criteria were women who had already had menopause for at least 1 year from their last menstrual period, who still had natural teeth in their maxilla and mandible, who were able to communicate, and who were willing to participate in this study. The exclusion criteria were women with systemic diseases, who were former smokers and alcoholics, who had received hormone therapy within the past 5 years, and who had had a hysterectomy. This study was approved by the Ethical Committee of the Faculty of Dentistry, Universitas Indonesia. All of the subjects signed informed consent forms before joining this study.

The risk of osteoporosis was determined by the mandibular bone density index. This index determines the risk of osteoporosis in subjects by assessing their age, duration of menopause, body mass index, history of hormonal therapy, duration of daily sun exposure, daily activity, and calcium intake. The subjects were classified into three groups: Osteoporosis (high risk), osteopenia (medium risk), and normal (low or no risk). A score from −9 to 25 meant osteoporosis, 26–52 meant osteopenia, and 53–95 was normal [14].

A periodontal examination was carried out for all subjects, and the following measurements were recorded to determine the level of CAL. CAL was measured from the cemento-enamel junction to the base of the pocket using a periodontal probe. All of the measurements were assessed at six sites per tooth: Mesiobuccal, midbuccal, distobuccal, mesiolingual, midlingual, and distolingual.

A syringe was used to draw 5 mL of venous blood, which was then centrifuged for 10 min. The samples were stored in small capped vials for long-term use at −20°C until tested. The serum was examined by the ELISA method, performed at Laboratorium Terpadu, Faculty of Medicine, Universitas Indonesia, Jakarta.

The data were analyzed using SPSS software from IBM. A normality test was performed. The correlations of age, serum osteocalcin level, and CAL with the osteoporosis risk were tested using a Spearman correlation test. Only p<0.05 was considered to be statistically significant, and a positive value showed a positive correlation. Comparison of serum osteocalcin levels and CAL to be higher in postmenopausal women with a high risk of osteoporosis than in the normal and osteopenia groups.

RESULTS
Seventy-one postmenopausal women ranging in age from 48 to 87 years participated in this study. The subjects were classified into three groups: Normal, with 29 subjects (40.28%); osteopenia, with 23 subjects (31.94%); and osteoporosis, with 19 subjects (26.39%). The mean values of the serum osteocalcin level and CAL for all three groups are presented in Table 1. The osteoporosis group had a higher mean age, mean serum osteocalcin level, and mean CAL than the other groups.

To investigate the correlations between the serum osteocalcin and CAL levels and the osteoporosis risk, the data were analyzed with a Spearman correlation test. Table 2 summarizes that there was a positive correlation between CAL and the osteoporosis high-risk status (r=0.32; p<0.05), but there was no correlation between serum osteocalcin levels and the osteoporosis risk (p>0.05).

Table 3 summarizes that there was no difference in the osteocalcin levels among subjects with mild, moderate, and severe CAL. The serum osteocalcin level was higher in those with mild and moderate CAL than with severe CAL. These results suggest that there is no statistically significant difference in the serum osteocalcin levels of the subjects with mild, moderate, and severe CAL (p>0.05).

DISCUSSION
This study was conducted in postmenopausal women because there is a strong relationship between menopause and osteoporosis. In postmenopausal women, hormonal changes cause an increase in receptor activator of nuclear factor Kappa-B ligand (RANKL), as does osteoclast activity. As a consequence, there is a shift from bone remodeling toward bone resorption that leads to osteoporosis [15].

The World Health Organization has determined that dual-energy X-ray absorptiometry is the gold standard for diagnosing osteoporosis. In this study, we used a questionnaire that determined the subjects’ risk factors for osteoporosis (the mandibular bone density index) [14]. This method was used because the index was developed based on a scoring model that consists of risk factors for osteoporosis. The index has a sensitivity of 77.06% and a specificity of 78.45% [14].

In individuals with osteoporosis, a low BMD in the jawbones may be associated with low systemic bone density. This low bone density or loss of bone density may lead to an increased susceptibility to the resorption of alveolar bone in areas with periodontitis. Systemic factors also modify the response of local tissue to periodontal infection and may also affect bone remodeling. Individuals with systemic bone loss have an increased systemic production of proinflammatory cytokines that may affect bone, including the maxilla and mandible. The result is a low bone density in the jawbones, caused by the increase in alveolar porosity, and more rapid alveolar bone resorption following an invasion by periodontal pathogens [16].

Bone remodeling occurs throughout the human lifespan. Bone is renewed by the bone turnover process, the products of which are known as bone turnover biomarkers and are classified as bone formation biomarkers and bone resorption biomarkers. Osteoblasts produce osteocalcin, which is important for calcification [17]. Serum osteocalcin is presently considered to be a valid marker of bone turnover when resorption and formation are coupled and a specific marker of bone formation when formation and resorption are uncoupled. Osteocalcin may be involved in recruiting osteoclasts to the sites of newly formed bone and thus may function as a negative regulator [18].

Table 1 summarizes that there is a tendency for serum osteocalcin levels and CAL to be higher in postmenopausal women with a high risk of osteoporosis than in the normal and osteopenia groups. Elevated serum osteocalcin levels have been found during periods of rapid bone turnover, as seen in osteoporosis, multiple myeloma,

| Postmenopausal woman | Mean (SD) | Osteopenia (n=23) | Osteoporosis (n=19) |
|----------------------|----------|------------------|-------------------|
| Weight (kg)          | 56.55 (7.86) | 62.26 (6.34) | 66 (6.81) |
| Height (cm)          | 156.3 (7.86) | 159.2 (7.34) | 158 (6.91) |
| BMI                  | 25.3 (0.81) | 26.5 (0.94) | 27.8 (1.03) |
| Serum osteocalcin (ng/mL) | 0.87 (0.94) | 0.86 (1.23) | 1.03 (1.32) |
| CAL (mm)             | 1.03 (0.94) | 1.03 (1.23) | 1.03 (1.32) |

SD: Standard deviation, CAL: Clinical attachment loss
Table 2: Correlations of serum osteocalcin and CAL levels with osteoporosis risk status

| Osteoporosis risk status          | n  | r      | p    |
|----------------------------------|----|--------|------|
| Age                              | 71 | 0.56*  | 0.001* |
| Serum osteocalcin                | 0.01| 0.92  |
| CAL                              | 0.32* | 0.01* |

Spearman test, *p<0.05 significance. CAL: Clinical attachment loss

Table 3: Comparison of serum osteocalcin levels in subjects with different severities of CAL

| Severity of CAL       | Osteocalcin (ng/mL) mean (SD) | p    |
|-----------------------|-------------------------------|------|
| Mild (1–2 mm)         | 0.63 (0.45)                   | 0.31 |
| Moderate (3–4 mm)     | 1.33 (1.63)                   |      |
| Severe (≥5 mm)        | 0.61 (0.37)                   |      |

Kruskal-Wallis test, *p<0.05 significance. CAL: Clinical attachment loss

There is a positive correlation between periodontal attachment loss and osteoporosis high-risk status.
