ABSTRACT

To date, more than 750 planets have been discovered orbiting stars other than the Sun. Two sub-classes of these exoplanets, “hot Jupiters” and their less massive counterparts “hot Neptunes,” provide a unique opportunity to study the extended atmospheres of planets outside of our solar system. We describe here the first far-ultraviolet transit study of a hot Neptune, specifically GJ 436b, for which we use Hubble Space Telescope/Space Telescope Imaging Spectrograph Lyα spectra to measure stellar flux as a function of time, observing variations due to absorption from the planetary atmosphere during transit. This analysis permits us to derive information about atmospheric extent, mass-loss rate from the planet, and interactions between the star and planet. We observe an evolution of the Lyα lightcurve with a transit depth of GJ 436b from 8.8% ± 4.5% near mid-transit, to 22.9% ± 3.9% ∼ 2 hr after the nominal geometric egress of the planet. Using data from the time-tag mode and considering astrophysical noise from stellar variability, we calculate a post-egress occultation of 23.7% ± 4.5%, demonstrating that the signature is statistically significant and of greater amplitude than can be attributed to stellar fluctuations alone. The extended egress absorption indicates the probable existence of a comet-like tail trailing the exoplanet. We calculate a mass-loss rate for GJ 436b in the range of 3.7 × 10^-6–1.1 × 10^-9 g s^-1, corresponding to an atmospheric lifetime of 4 × 10^11–2 × 10^14 yr.

Key words: planets and satellites: atmospheres – planets and satellites: individual (GJ 436b)

1. INTRODUCTION

Since the mid-1990s, astronomers have been regularly discovering planets orbiting other stars using the radial velocity method (Mayor & Queloz 1995). Many of these planets called “hot Jupiters” are massive (>50 M_J, >0.15 M_Jup), orbit very close to their host stars (<0.05 AU), and have orbital periods of only a few days (Seager & Deming 2010). Less massive planets (10–50 M_J, 0.03–0.15 M_Jup, 0.6–3 M_Nep) that also orbit very close to their host stars are similarly named after their solar system analogs, “hot Neptunes.” The majority of the first exoplanet detections were “hot Jupiters” and “hot Neptunes” because there is a detection bias in favor of this type of planet. Since they are large (in mass and radius) and orbit close to their host stars, they are more easily detected in both radial velocity and transit searches.

In 1999, Henry et al. (2000) discovered the first transiting exoplanet, HD 209458b. Transiting exoplanets provide an opportunity to study the composition and structure of their atmospheres, because as these planets pass in front of their host star, their atmosphere blocks a portion of the starlight. Spectroscopy at IR and optical wavelengths has led to the discovery of Na i, H_2O, CH_4, and CO (Charbonneau et al. 2002; Tinetti et al. 2007; Swain et al. 2008; Swain et al. 2009) in the atmospheres of exoplanets, shifting the emphasis of exoplanet studies toward detecting and characterizing their atmospheres (Koskinen et al. 2010).

While many studies utilize IR (700 nm–3 μm; e.g., Deming et al. 2007) and optical (400–700 nm; e.g., Butler et al. 2004) wavelengths, UV (1000–4000 Å) observations provide a unique opportunity to characterize exoplanet exospheres. Stellar FUV and EUV radiation heats, accelerates, and, when the photon energies exceed 13.6 eV, ionizes the hydrogen in the upper atmosphere (Murray-Clay et al. 2009). When the thermal energy exceeds the gravitational potential energy (3kT/2 > GMm/r), the heated gas expands (Lammer et al. 2003) and likely escapes from the planet. These inflated atmospheres contain many atomic species, such as H, C+, O, and Si2+, that absorb the stellar radiation in UV resonance lines (Vidal-Madjar et al. 2004; Linsky et al. 2010). Because the envelopes of these exoplanets are inflated, the geometric area in their UV resonance lines is larger than that of molecules detected in the IR and optical, and the transit depth will be larger. Such data permit us to understand the composition of extended exoplanet atmospheres.

Vidal-Madjar et al. (2003) used the H I Lyα 1215 Å emission line of HD 209458 to obtain the first evidence of an inflated exoplanetary atmosphere, revealing a transit depth in Lyα (15% ± 4%) several times that of the geometric depth determined from the optical transit (1.58% ± 0.18%). The Lyα transit depth indicates an atmosphere that extends beyond its Roche lobe, likely indicating atmospheric escape. Subsequent UV observations have demonstrated the existence of enlarged envelopes in the spectral lines of O I (Vidal-Madjar et al. 2004), and Si2+ (Linsky et al. 2010) around HD 209458b, and later observations identified a similar absorption spectrum from the atmosphere of HD 189733. Observations of HD 189733 have been used to detect extended atmospheres in lines of H i (Lecavelier des Etangs et al. 2010), O I, and possibly C II (Ben-Jafel & Ballester 2013). The non-detection of an extended Lyα envelope in 2010 April, indicated significant variations in the evaporation rate of H i (Lecavelier des Etangs et al. 2012).

UV transit observations are often used to infer mass-loss rates of hot Jupiters, from which we may learn about the evolution of exoplanets and their atmospheres. Vidal-Madjar
et al. (2003) used a particle simulation to limit the mass loss rate of HD 209458b to \( \geq 10^{10} \) g s\(^{-1}\). Linsky et al. (2010) performed a theoretical calculation to find mass-loss rates in the range of \((8–40) \times 10^{10} \) g s\(^{-1}\). Lecavelier des Etangs et al. (2010) used their data of HD 189733b and a numerical simulation to find a best fit mass-loss rate of \(10^{11} \) g s\(^{-1}\). Ehrenreich & Désert (2011) compare the planet gravitational potential energy to the stellar X/EUV energy deposited in the atmosphere and estimate the mass-loss rate for WASP-12b to be \(2.5 \times 10^{11} \) g s\(^{-1}\).

Many theoretical models have been developed to explain the evaporation process and to predict the mass-loss rates for various hot Jupiters. Lammer et al. (2003) used the heating rate from stellar X-ray and EUV radiation to estimate a mass-loss rate for HD 209458b of \(\sim 10^{12} \) g s\(^{-1}\). Yelle (2004; later revised in Yelle 2006) included chemical calculations to estimate a mass-loss rate. Cooling from H\(^2\) and ionization of H to H\(^+\), reducing the amount of stellar energy available for heating, led to a lower mass-loss rate of \(4.7 \times 10^{10} \) g s\(^{-1}\). Similar calculations by García Muñoz (2007) determined mass-loss rates in the range \(6–15 \times 10^{10} \) g s\(^{-1}\) depending on the level of stellar activity. Holmström et al. (2008) attributed a portion of the Ly\(\alpha\) absorption to protons from the stellar wind that have been neutralized by charge exchange with hydrogen atoms in the planetary atmosphere and calculated a mass-loss rate of \(7 \times 10^8 \) g s\(^{-1}\). Guo (2013) calculated a mass-loss rate of \(4.3 \times 10^9 \) g s\(^{-1}\) using a two-dimensional model that assumed HD 209458b is tidally locked with one side of the planet always facing the star. Murray-Clay et al. (2009) modeled the atmospheric escape of a theoretical hot Jupiter (similar to HD 209458b) that includes realistic heating and cooling rates, ionization balance, tidal gravity, and pressure confinement by the stellar wind. They found a mass-loss rate of \(2 \times 10^{10} \) g s\(^{-1}\). In the above examples, the calculated mass-loss rates vary by several orders of magnitude depending on what physics is considered and on the values of system parameters (for example the amount of stellar EUV flux).

The manner in which the atmospheric envelope interacts with the stellar wind determines the structure of the gas around the planet. High-velocity neutral hydrogen escaping from the atmosphere trails the planet absorbing Ly\(\alpha\) photons until the hydrogen is ionized by the stellar EUV flux or charge exchanges with stellar wind protons. The trailing material may cause the hydrogen Ly\(\alpha\) transit to last longer than the optical occultation.

The formation of a comet-like tail trailing the planet was first suggested by Schneider et al. (1998). Models of neutral hydrogen escaping from the hot Jupiter HD 209458b and HD 189733b by Bourrier & Lecavelier des Etangs (2013) support this structure. The evaporating super-Mercury exoplanet KIC 12557548b likely has a dusty comet-like tail (Rappaport et al. 2012; Budaj 2013) and the extreme hot Jupiter WASP-12b is losing sufficient mass to completely obscure its host star’s emission in the cases of the Mg \(\alpha\) h and k lines (Haswell et al. 2012).

Vidal-Madjar et al. (2003) observed absorption out to Doppler velocities \(\pm 100\) km s\(^{-1}\) from the Ly\(\alpha\) line center of HD 209458b, and absorption has been seen at velocities as large as \(-230\) km s\(^{-1}\) from the center of Ly\(\alpha\) for HD 189733b (Lecavelier des Etangs et al. 2012). Thermal velocities can only account for absorption out to \(\sim 10\) km s\(^{-1}\) (Murray-Clay et al. 2009). Models by Lecavelier des Etangs et al. (2012) suggest that stellar radiation pressure can accelerate particles up to 120 km s\(^{-1}\), but an additional mechanism is necessary to explain the large observed radial velocities. Charge exchange with hot, slow \(<50–100\) km s\(^{-1}\) stellar wind protons can produce the observed velocities (Holmström et al. 2008; Ekenbäck et al. 2010; Tremblin & Chiang 2013). Holmström et al. (2008) proposed that the absorption in neutral hydrogen at high velocities is due to charge exchange between protons from the stellar wind and planetary neutral hydrogen. The planetary hydrogen is ionized and the stellar wind proton becomes neutral hydrogen maintaining its large velocity.

1.1. Previous Studies of GJ 436b

A promising exoplanet for UV transit observations is GJ 436b, a hot Neptune, \((M = 0.07 M_{\text{Jup}})\), orbiting an M2 dwarf at 0.029 AU with a period of 2.6 days. GJ 436b is particularly promising because it is very close to Earth, at a distance of only 10.2 pc. The properties of the system are summarized in Table 1. GJ 436b was discovered by Butler et al. (2004) using the radial velocity method, but was later found to be transiting its host star (Gillon et al. 2007).

In 2010 Spitzer observed GJ 436 during several secondary transits in six bands from 3.6 to 24 \(\mu\)m. Using a Metropolis–Hastings Markov-chain Monte Carlo (MCMC) model, Stevenson et al. (2010) explored a wide range of parameter space to determine the best-fit compositional models.
They found a high CO abundance and a deficiency of CH$_4$ relative to thermochemical equilibrium. Madhusudhan & Seager (2011) also used MCMC to confirm the overabundance of CO and CO$_2$, and a slight underabundance of H$_2$O, as compared to equilibrium chemistry with solar metallicity. They explained the observed abundances by a combination of high metallicity (~10$^{-4}$ solar) and vertical mixing. Observations by Knutson et al. (2014) indicate an effectively featureless transmission spectrum, ruling out cloud-free, hydrogen-dominated atmosphere models. The measured spectrum is consistent with either a high cloud or haze layer or with a relatively hydrogen-poor atmospheric composition. Hu & Seager (2014) find that hot Neptunes, like GJ 436b, are likely to have thick atmospheres that are not hydrogen dominated, but are water-rich or hydrocarbon-rich depending on their C/O ratio. Using limited Hubble Space Telescope (HST) Space Telescope Imaging Spectrograph (STIS) data of the stellar Ly$_\alpha$ flux, Ehrenreich et al. (2011) developed numerical simulations to determine the transit signature of GJ 436b for various assumed mass-loss rates. They predicted an 11% transit depth in Ly$_\alpha$ for a mass-loss rate of 10$^{10}$ g s$^{-1}$. The analysis we have conducted is the first to place observational constraints on the mass-loss rate of GJ 436b or any other Neptune-mass exoplanet.

In this paper, we present and analyze transit observations of GJ 436b in Ly$_\alpha$ observed with STIS on the HST. In Section 2 we describe the data sets used and the reduction process, and how we created the lightcurves and velocity profiles. We present the lightcurve and velocity profile for Ly$_\alpha$ in Section 3 along with the measured absorption depths. In Section 4 we discuss the structure of the system and calculate a range of mass-loss rates. We summarize our results in Section 5.

2. OBSERVATIONS AND DATA ANALYSIS

2.1. GJ 436 Data

The HST/STIS transit data of GJ 436 were obtained with the G140M grating using a long slit with dimensions 52$''$ x 0$''$.1. We selected a central wavelength of 1222 Å, covering the spectral range of 1194–1249 Å with a spectral resolution of about 25 km s$^{-1}$. The data were taken with the FUV-MAMA detector using the time-tag mode. Table 2 summarizes all of the observations. Our four orbit per transit observing cadence is comparable to that used by Lecavelier des Etangs et al. (2012) for velocity resolved observations of the extended hydrogen atmosphere of the hot Jupiter HD 189733b with the same STIS grating configuration. Given an error of 2%, the relative photometric accuracy of STIS, issues of persistence and instrumental settling are less significant when observing the 10% UV transit signal of the exosphere compared to the <1% near-IR molecular diagnostics of the lower atmosphere.

| Data Set | Exp. Time | Day | Start (UT) | Phase$^{a,b}$ |
|----------|-----------|-----|------------|--------------|

Notes.

$^a$ Phases shown are at the time of mid-exposure.

$^b$ A phase of 0:00:00 corresponds to the center of the primary optical transit.

We reduced the GJ 436 data using CALSTIS v2.40 (2012 May 23). For the final two exposures, the CALSTIS pipeline did not correctly extract the one-dimensional spectrum (the “x1d” file) from the two-dimensional data. We therefore manually extracted the one-dimensional spectrum for all four exposures. Since in the “x2d” file, the source was located at pixels 481–491, we subtracted a background ribbon at pixels 492–502 from the source data (see Figure 1). A wavelength solution was then calculated by using the reference wavelength, reference pixel, and dispersion from the header. Finally, we obtained fluxes by multiplying by the angular area covered by the pixels and an additional scale factor (determined empirically by matching to a correctly extracted spectrum from the “x1d” files for the first two exposures).

2.2. Data Analysis

To characterize the transit, we take two complementary approaches. The first is the creation and analysis of lightcurves. This approach allows us to study the transit with higher time resolution. The lightcurve creation method is described in detail below. In the second method, we analyze the spectral difference between the pre-ingress, transit, and post-egress data. This method maintains the velocity resolution of the data. We also created velocity profiles for Ly$_\alpha$. We compared the pre-ingress spectrum to the transit and post-egress spectra as a function of velocity. We also looked at the difference between the spectra (pre-ingress minus post-egress, such that absorption is a positive difference) versus velocity. We then calculated the post-egress depth by integrating this difference spectrum.

2.2.1. Light Curve Creation

The data were obtained over a time period that covers portions of the exoplanet orbit before, during, and after transit. For every exposure, we calculated the orbital phase of the exoplanet (in hours) at the time of mid-exposure using the ephemeris data in Table 1, such that mid-transit occurs at phase 0 hr.

We used the one-dimensional spectra extracted from the “x2d” files, as described in Section 2.1, and integrated the flux for different wavelength portions of the Ly$_\alpha$ line. Avoiding the center of the Ly$_\alpha$ line, where noise from the airglow subtraction is high, we integrated the flux from the blue and red sides of the line separately. The wavelength range for the integration of each wing of Ly$_\alpha$ is shown in Table 3. We then created lightcurves for each wing by plotting the total flux versus orbital phase.
Figure 2. Normalized Ly\(\alpha\) count rates for GJ 436. Blue points show the flux from the blue wing of Ly\(\alpha\) and red points show the flux from the red wing. Filled points are calculated from the time-tag data, while the open circles are from the entire exposure. Error bars indicate \(\pm 1\)\(\sigma\). The black dotted line indicates the normalized flux level, while the black dashed line shows the transit curve as calculated from the optical transit parameters. The green and pink lines shows the predicted transit signature of GJ 436b as calculated by Ehrenreich et al. (2011) for mass-loss rates of \(10^9\) and \(10^{10}\) gs\textsuperscript{−1} respectively. Vertical dashed lines indicate first and fourth contacts.

We also used the “tag” files containing the time-tag data to calculate a time series of the data in 12 minute increments. The “tag” files contain a photon event list giving the time and detector coordinates of each recorded count. Using the known positions of the source and the background as well as the wavelength solution (from the “x2d” files), we keep only events with detector positions that correspond to source or background counts within specified wavelength ranges. These data are then binned in time. We found that a bin size of 12 minutes is a suitable compromise between signal-to-noise and time resolution. This additional time resolution allows us to better assess the lightcurve for stellar variability (Loyd & France 2014). We incorporated these time-tag data in the Ly\(\alpha\) lightcurve analysis for GJ 436.

3. RESULTS AND DISCUSSION

3.1. GJ 436b Transit

We show the Ly\(\alpha\) lightcurve for GJ 436 in Figure 2 and the \(L\alpha\) velocity profile in Figure 3. Table 4 shows the transit depths extracted from these figures. The transit depths are identical for the two procedures (because the reference spectrum and the integration method are the same), however, the spectral analysis results in somewhat larger errors, due to the extra step of subtracting prior to normalizing and integrating. We will use the higher time resolution lightcurve data to analyze the transit depth. For GJ 436b we see a mid-transit depth of 16.6\% ± 7.2\% in the blue wing and 4.5\% ± 5.7\% in the red wing. This corresponds to an occulting disk of 5.0 \(R_p\) and 2.6 \(R_p\) respectively, both smaller than the Roche lobe radius of 6.1 \(R_p\). When both wings are combined, the mid-transit depth is 8.8\% ± 4.5\%, corresponding to an equivalent opaque occulting disk of 3.6 \(R_p\). The asymmetry in the absorption can be explained by charge exchange of the stellar wind with the atmosphere. As viewed from Earth, only the stellar wind traveling toward us can be observed, causing excess absorption blue-ward of line center. This type of asymmetry, with more absorption in the blue wing, is also seen in the Ly\(\alpha\) absorption during transit from HD 209458b (Vidal-Madjar et al. 2003) and HD 189733b (Lecavelier des Etangs et al. 2012).

Interestingly, the Ly\(\alpha\) transit extends much later in phase than the optical transit. We examine these data for the possibility of extended egress, finding post-egress depths of 29.9\% ± 6.4\% in the blue wing, 19.1\% ± 5.0\% in the red wing, and 22.9\% ± 3.9\% for both wings combined \(\sim 2\) hr after mid-transit and about 1.5 hr after fourth contact. The time-tag data points are presented in Table 5. These data corroborate the detection of both the transit and extended egress, as three of the four transit data points and all of the post-egress data points show a transit detection, although...
large variations in the blue-wing time-tag data are observed near mid-transit.

3.2. Extended Egress in GJ 436

To determine whether or not the extended egress is real, we consider the time-tag data. We form the null hypothesis that the data are Gaussian distributed and the apparent occultation is random noise. We use the average of the error bars on the time-tag data as the standard deviation for the Gaussian distributions \( \sigma_{\text{blue}} = 0.1092, \sigma_{\text{red}} = 0.08930 \), both with a mean of unity. Assuming these distributions, we determined the probability of finding four consecutive points lower than the highest point in the set of four at the deepest transit depth, which is located at phase \( \sim 2 \) hr \((x_{\text{blue}} = 0.3003, x_{\text{red}} = 0.1187 \) below the mean). We did this by randomly picking 14 points from the specified Gaussian distribution and counting how many trials out of \( 10^7 \) had four consecutive points outside the requisite range. For the parameters determined for the blue wing, none of the \( 10^7 \) trials had four consecutive points. For the red wing distribution, we found a probability of \( 9.31 \pm 0.76 \times 10^{-5} \) to randomly produce the result. We therefore conclude that the deep, extended egress signal seen in Figure 2 is real and not due to random statistical variations.

3.3. Stellar Variability of GJ 436

While we have determined that the post-egress detection is not due to statistical noise, we have not yet considered whether the drop in flux could be due to stellar variability, as opposed to atmospheric absorption from GJ 436b. To address this issue, we look at a resonance line from N\( \alpha \), an ion that we do not expect to find in the atmosphere of the exoplanet. For the N\( \alpha \) time-tag data points we find \( \text{rms} = 0.2765 \), while the average value of the \( 1\sigma \) error bar for those points is 0.4010. We conclude that the signal to noise is too low for the N\( \alpha \) doublet to be a suitable tracer of stellar variability. Similarly, there was not enough flux in the Si\( \text{\textit{I}} \) line to be measurable above the noise.

Instead we look to the literature to assess the potential magnitude of stellar variability. Loyd & France (2014) studied time variability in the C\( \text{\textit{II}} \), Si\( \text{\textit{II}} \), and Si\( \text{\textit{IV}} \) resonance lines of 38 cool stars, including GJ 436. They did not attempt to characterize Ly\( \alpha \) line variability because geocoronal airglow cannot be removed reliably from their Cosmic Origins Spectrograph data. Instead we use their C\( \text{\textit{II}} \) emission line variability, because C\( \text{\textit{II}} \) has a similar formation temperature to Ly\( \alpha \) \((T_{\text{form}} \approx (1–3) \times 10^3 \) K; Dere et al. 2009). Loyd & France (2014) found that the mean-normalized chromospheric C\( \text{\textit{II}} \) line variability, excluding flare periods, in GJ 436 is \( 0.20_{\text{0.05}} \) on 60 s timescales. Our post-egress data cover a 48 minute time span. Assuming that the stellar variability is uncorrelated over time, the noise associated
with stellar fluctuations is estimated to be $0.20/\sqrt{48} = 0.0289$. Combining the eight post-egress time-tag data points and the photon noise with the upper limit on the noise expected from chromospheric variability, we find a 23.7% occultation with an uncertainty of 4.5%. From this we conclude that the post-egress detection is very likely real. Future observations over several transit cycles would be very valuable.

4. GJ 436 SYSTEM

4.1. Structure

Some models of the interaction between escaping gas from the exoplanet’s atmosphere and the stellar wind predict a comet-like tail extending behind the planet (Schneider et al. 1998; Bourrier & Lecavelier des Etangs 2013). The Lyα data support this type of structure in the GJ 436 system. A large, inflated cloud of gas trailing the planet could explain an occultation deeper than that observed in the optical and post-egress absorption long after optical transit.

In order to simulate the structure of the exoplanetary gas cloud at the orbit of GJ 436b, we attenuate the pre-ingress profile by a column of hydrogen and deuterium to match the post-egress spectrum. We search for a $\chi^2$ best fit neutral hydrogen column ([$\log(N_{H})$]) ranging from 14.0 to 19.0 in step sizes of 0.2 dex) for a grid of stellar covering fraction (assuming uniform optical thickness of the gas over the area covered and uniform emission of Lyα from the stellar disk) versus Doppler b value, $b = (2kT/m_H) + u^2/n_{\text{thr}}$. We assume a fixed D/H ratio of $1.5 \times 10^{-5}$ (Linsky et al. 2006). For the range of tested covering fractions and b values, we find two parameter regimes that provide a reasonable fit to the data. The first is a low covering fraction, high $N_{H1}$ model. The second is a high covering fraction low $N_{H1}$ model. We expect the second regime to be more physically plausible. The low covering fraction models require $N_{H1} \sim 10^{19}$ cm$^{-2}$. Assuming that the comet-like tail extends to a few times the orbital radius, $\sim 0.1$ AU in the line of sight (LOS) to the star, we find a number density $n_{H} \sim \text{few} \times 10^{7}$ cm$^{-3}$. This density is far above the estimates ($\sim 3 \times 10^{5}$ cm$^{-3}$) from comet-like tail models (Bourrier & Lecavelier des Etangs 2013). A column density of $N_{H1} = 10^{15}$ cm$^{-2}$, typical of the high covering fraction regime, converts to a number density $n_{H1} \sim \text{few} \times 10^{5}$ cm$^{-3}$.

Taking the high covering fraction and low $N_{H1}$ case as more plausible, acceptable fits to the post-egress Lyα spectrum require the Doppler b-parameter to be between 60 and 120 km s$^{-1}$. We require $b$ values in this range to fit the shape of the post-egress Lyα profile. For a typical atmospheric temperature of $10^4$ K, the thermal width is 13 km s$^{-1}$, requiring a superthermal velocity component of $\sim 50–110$ km s$^{-1}$ to explain such high b values. Charge exchange between stellar wind protons and planetary wind neutral H atoms will lead to neutral H atoms with high velocities. For a representative covering fraction of 0.8, we can then limit $\log(N_{H1})$ to 14–16. Figure 4 shows an example best fit attenuation profile with parameters within this range. These ranges are shown in Table 6.

To achieve a covering fraction of 0.8 requires a cloud of $R \approx 10R_{\text{planet}}$. Using the column density and b (to calculate the cross-section at the line core, $\sigma = (\sqrt{\pi}e^2/m_ec)(f\lambda_0/b))$, we can estimate the line center optical depth of the extended neutral hydrogen atmosphere (τ$\lambda_0 = N_{H1}$). For the ranges of $N_{H1}$ and b, we find $\tau_\lambda = 0.63–130$. Koskinen et al. (2010) predict the hydrogen cloud to be optically thick in the line wings, indicating

### Table 6

| Cloud Properties | Range |
|------------------|-------|
| Covering fraction | 0.7–0.9 |
| $b$ (km s$^{-1}$) | 60–120 |
| $\log(N_{H1}$ (cm$^{-2}$)) | 14–16 |
| $\tau_\lambda$ | 0.63–130 |
that our models with the lowest columns and higher b (which give the higher $\tau_r$,s) are more physically representative.

### 4.2. GJ 436b Mass-Loss Rate

#### 4.2.1. Spherical Mass-loss

We first calculate the mass-loss rate for GJ 436b by assuming a spherically symmetric envelope around the planet that blocks a portion of the stellar surface. We consider an LOS toward the center of the star that passes through the exoplanet’s atmosphere a distance $p$ from the center of the planet. We measure $x$ along the LOS and $r$ along from the center of the planet (see Figure 5). For a spherical outflow with a constant mass-loss rate, the mass flux in neutral hydrogen from the planet is

$$ M_H = 4\pi r^2 m_H n_H(r), $$

where $v$ is the outflow velocity at $r$. The optical depth at the line center along this LOS is

$$ \tau_0 = \sigma \int_0^\infty n_H(x) dx, $$

where $n_{H_1}$ is the number density of neutral hydrogen, $\sigma$ is the absorption cross section. Combining Equations (1) and (2) yields

$$ \tau_0 = \frac{\sigma M_{H_1}}{4\pi m_H} \int_0^\infty \frac{dx}{vr^2} \Rightarrow M_{H_1} = \frac{4\pi m_H \tau_0}{\sigma} \left[ \int_0^\infty \frac{dx}{vr^2} \right]^{-1}. $$

In the integrand, the $r^{-2}$ factor gives the highest weight to $v$ values where the LOS passes closest to the planet (smallest $r$). Thus, for an order-of-magnitude calculation $v$ may be taken out of the integral and replaced with a value representative of that expected near the radius at closest approach, $r = p$, between the LOS and planet. (This assumes $v$ does not drop precipitously at large $r$, consistent with the models of Murray-Clay et al. 2009.) Bringing $v$ out of the integral, we are able to find an analytical solution. From Figure 5 we can use $r^2 = (x - a)^2 + p^2$, where $a$ is the star–planet distance, to evaluate the integral in Equation (3).

$$ \int_0^\infty \frac{dx}{r^2} = \int_0^\infty \frac{dx}{(x - a)^2 + p^2} = \frac{\pi}{2p} + \frac{1}{p} \arctan \left( \frac{a}{p} \right). $$

Since only LOSs that intersect the stellar disk, $p < R_*$, are of interest, and for GJ 436 a/R* = 13.34, $\arctan(a/p)$ may be taken to be $\pi/2$ to good accuracy, so that the integral in Equation (4) simplifies to $\pi/p$. Thus

$$ M_{H_1} \approx \frac{4\pi \nu m_H \tau_0}{\sigma_0}. $$

The cross section at line center is given by

$$ \sigma_0 = \frac{\sqrt{\pi} e^2}{m_e c \Delta\nu_D} f $$

$f$ = 0.4161 is the oscillator strength, $m_e$ is the electron mass, and $\Delta\nu_D$ is the Doppler width given by

$$ \Delta\nu_D = \frac{v_0}{c} \left( \frac{2kT}{m_H} + v_{\text{turb}}^2 \right)^{1/2} = \frac{b}{\tau_0}. $$

Given the range of $b$ values determined in Section 4.1 ($b = (60-120 \text{ km s}^{-1})$, we limit the cross section at Ly$\alpha$ to $\sigma_0(H) = 6.3 \times 10^{-15} - 1.3 \times 10^{-14}$.

Assuming the absorption is due to an optically thin cloud covering the star, we consider annuli of area $2\pi p dp$ centered on the planet. Each annulus absorbs a fraction of the light from the stellar disk equal to $dF/\nu = 2\pi p dp$$(1 - e^{-\tau_0})/\nu_d H$.

$$ \delta = \frac{\int_0^{R_r} dF}{\nu_d H} = \frac{2}{R_*^2} \int_0^{R_r} (1 - e^{-\tau_0}) dp. $$

According to Murray-Clay et al. (2009), $\tau_0 < 0.1$ for $p > 1.5R_p$, so using the small $\tau$ approximation, Equation (8) becomes

$$ \delta = \frac{2}{R_*^2} \int_0^{R_r} p \tau_0 dp. $$

Using Equation (5) this becomes

$$ \delta \approx \frac{2}{R_*^2} \frac{M \sigma_0}{4 m} \int_0^{R_r} \frac{dp}{\nu} \approx \frac{2}{R_*^2} \frac{M \sigma_0}{4 m \nu} (R_* - R_p) \approx \frac{2}{R_*} \frac{M \sigma_0}{4 m \nu}. $$

While Murray-Clay et al. (2009) predict $\delta$ to vary by a factor of a few over the range of $p$ considered here, we have approximated $\nu$ to be constant with $p$. We have also neglected the $R_p \ll R_*$ term. Solving for the mass loss rate, we write

$$ M \approx \frac{2\delta R_* m \nu}{\sigma_0}. $$

Following Murray-Clay et al. (2009), we adopt $\nu = 10 \text{ km s}^{-1}$, approximating to the thermal velocity of hydrogen at $10^4$ K. We use the observed mid-transit depth $\delta = 0.088 \pm 0.045$. Thus, these observations, for our range of $b$ values, bound the mass-loss rate in neutral hydrogen to

$$ M_{H_1} = 3.7 \times 10^{6}-2.3 \times 10^{6} \text{ g s}^{-1}. $$

The mass-loss rate depends linearly on the $b$ value. So, if the $b$ value at the exobase, where the wind is launched, differs from $b$ values we have calculated, the mass-loss rate would differ correspondingly. Because the planet is so close to its host star, the EUV flux and charge exchange with the stellar wind will ionize most of the escaping hydrogen and only a small fraction will be neutral in the outer atmosphere. Koskinen et al. (2013) model the $H$ and $H^+$ density in the atmosphere of HD 209458b as a function of planetary radius. In the upper atmosphere ($R \approx 5R_p$) the neutral fraction is $\sim 0.1$. Assuming
similar ionization conditions in the extended atmosphere of GJ 436b, we correct for this neutral fraction, and calculate a total mass-loss rate

\[ M = 3.7 \times 10^6 - 2.3 \times 10^7 \text{ g s}^{-1}. \]  

Assuming the structure of GJ 436b is similar to that of Neptune, and the atmosphere comprises 5%–15% of the mass of the planet (Guillot 1999), and that the mass-loss rate is constant in time, this range of mass-loss rates gives a range of atmospheric lifetimes of \(9.5 \times 10^{12} - 1.8 \times 10^{14}\) yr, indicating that the atmosphere is stable over the lifetime of the star.

4.2.2. EUV Heating to PdV Work

We also calculate the mass-loss rate following the analytical argument of Murray-Clay et al. (2009). We first calculate the amount of stellar EUV flux available to heat the atmosphere,

\[ E_{\text{heat}} = \epsilon \pi F_{\text{EUV}} R_p^2 \]  

(13)

Here \(\epsilon\) is an efficiency factor, \(F_{\text{EUV}}\) (in erg cm\(^{-2}\) s\(^{-1}\)) is the stellar flux at the orbit of the planet from 300 to 912 Å (where the photoionization cross-section for hydrogen is largest; Murray-Clay et al. 2009), and \(R_p\) is the planetary radius. Using the model scaling relations of Linsky et al. (2014), we estimated the EUV flux based on the reconstructed Ly\(\alpha\) luminosity (France et al. 2013). These calculated EUV luminosities are shown in Table 7. We then consider the PdV work required to liberate a unit mass from the gravitational well of the planet:

\[ \frac{P \Delta V}{\rho R_p^2 h} \sim \frac{P R_p^3}{\rho R_p^2 h} \sim \frac{\rho H R_p^3}{\rho R_p^2 h} \sim GM_p R_p. \]  

(14)

The mass-loss rate is then the ratio of the heat available to the work required to lift out mass:

\[ M = \frac{\epsilon \pi F_{\text{EUV}} R_p^2}{GM_p / R_p} = \frac{\epsilon \pi F_{\text{EUV}} R_p^3}{GM_p} = 1.1 \times 10^9 \text{ g s}^{-1}, \]  

(15)

corresponding to a lifetime of \(4 \times 10^{11}\) yr. Here we have assumed an efficiency \(\epsilon = 0.3\) and extrapolated an EUV flux \(F_{\text{EUV}} = 607\) erg cm\(^{-2}\) s\(^{-1}\) from the reconstructed intrinsic Ly\(\alpha\) flux. This argument is valid only if we are in the EUV driven, as opposed to X-ray driven, evaporation regime. According to Owen & Jackson (2012) for a Neptune-mass planet with a density of 1 g cm\(^{-3}\) at a separation of 0.025 AU (for GJ 436b: mass = 1.35 \(M_{\text{Neptune}}\), density = 1.69 g cm\(^{-3}\), separation = 0.029 AU) the critical X-ray luminosity at which the planetary wind will transition from X-ray driven to EUV driven is \(\sim 8 \times 10^{28}\) erg s\(^{-1}\). Kashyap et al. (2008) measure the X-ray luminosity of GJ 436 to be \(1.4 \times 10^{27}\) erg s\(^{-1}\), two orders of magnitude lower than the transition value, placing GJ 436b well into the EUV driven evaporation regime.

These two methods give results that differ by two orders of magnitude. This is not surprising given that mass-loss calculations for HD 209458 can vary by four orders of magnitude depending on method. Our range of mass-loss values are roughly consistent with the models of Ehrenreich et al. (2011). Their model transit curves can be seen in Figure 2. They predict a transit depth of 11% for a mass-loss rate of \(10^{10}\) g s\(^{-1}\). Their calculation of the mass-loss rate was based on the measured stellar X-ray (5–124 Å) luminosity, \(\log(L_X (\text{erg s}^{-1})) = 26.85 \pm 0.65\) (Hünsch et al. 1999). However, this X-ray luminosity arises in the stellar corona, and may not be representative of the majority of the longer wavelength EUV flux from GJ 436, which is likely dominated by Lyman continuum emission from the transition region and upper chromosphere (Linsky et al. 2014). We find EUV luminosities lower than Ehrenreich et al. (2011), especially at wavelengths where the photoionization cross-section for hydrogen is largest (300–900 Å; Murray-Clay et al. 2009). Their calculation also depends linearly on the heating efficiency (\(\eta\), similar to \(\epsilon\) above) in the atmosphere, a parameter that is not well constrained. For \(\eta = 0.15\) they calculate \(M = 1.60 \times 10^9\) g s\(^{-1}\), but this mass-loss rate can range between \(1.07 \times 10^9\) g s\(^{-1}\) and \(1.07 \times 10^{10}\) g s\(^{-1}\) for \(\eta\) between 0.01 and 1. Uncertainties in the neutral fraction that we use in our first calculation, \(\epsilon\) in our second calculation, and the parameters of the Ehrenreich et al. (2011) calculation leave a wide range for the possible mass-loss rate of GJ 436b.

5. SUMMARY

We have analyzed new observations of GJ 436. We used HST/STIS data to detect and characterize the extended atmosphere of GJ 436b for the first time. We detected 8.8% ± 4.5% absorption in the Ly\(\alpha\) line at mid-transit, and used this transit depth to calculate a mass-loss rate in the range 3.7 \(\times 10^{10}\)–1.1 \(\times 10^{10}\) g s\(^{-1}\), corresponding to an atmospheric lifetime of \(4 \times 10^{11} - 2 \times 10^{14}\) yr. We also detected strong absorption after the optical transit with a depth of 23.7% ± 4.5%. We confirmed that this extended egress is not a statistical fluctuation, and showed that it is unlikely to be due to stellar variability; the most likely explanation is that GJ 436b is trialed by a comet-like tail of neutral hydrogen.

This material is based upon work supported by the National Science Foundation Graduate Research Fellowship Program under grant No. DGE 1144083. The data presented here were obtained as part of HST Observing program 12034. K.F. acknowledges support through a NASA Nancy Grace Roman Fellowship during this work.
