Mechanistic Origins of the pH Dependency in Au-Catalyzed Glycerol Electro-oxidation: Insight from First-Principles Calculations

Anand M. Verma, Laura Laverdure, Marko M. Melander, and Karoliina Honkala*

ABSTRACT: Electrocatalytic oxidation of glycerol (EOG) is an attractive approach to convert surplus glycerol to value-added products. Experiments have shown that EOG activity and selectivity depend not only on the electrocatalyst but also on the electrode potential, the pH, and the electrolyte. For broadly employed gold (Au) electrocatalysts, experiments have demonstrated high EOG activity under alkaline conditions with glyceric acid as a primary product, whereas under acidic and neutral conditions Au is almost inactive producing only small amounts of dihydroxyacetone. In the present computational work, we have performed an extensive mechanistic study to understand the pH and potential dependency of Au-catalyzed EOG. Our results show that activity and selectivity are controlled by the presence of surface-bound hydroxyl groups. Under alkaline conditions and close to the experimental onset potential, modest OH coverage is preferred according to our constant potential calculations. This indicates that both Au(OH)ads and Au can be active sites and they cooperatively facilitate the thermodynamically and kinetically feasible formation of glyceric acid thus explaining the experimentally observed high activity and selectivity. Under acidic conditions, hydroxide coverage is negligible and the dihydroxyacetone emerges as the favored product. Calculations predict slow reaction kinetics, however, which explains the low activity and selectivity toward dihydroxyacetone reported in experiments. Overall, our findings highlight that computational studies should explicitly account for pH and coverage effects under alkaline conditions for electrocatalytic oxidation reactions to reliably predict electrocatalytic behavior.

KEYWORDS: electro-oxidation, glycerol, electrocatalyst, electrolyte

INTRODUCTION

In this era of depleting fossil resources, the production of biofuels and specifically biodiesel has become immensely important. In biodiesel production via transesterification of triglycerides, glycerol emerges as a major byproduct, and accounts for approximately 10% of the total product mixture.1,2 The production of surplus glycerol has driven its market price down,3 and it has consequently been listed by the U.S. Department of Energy4 as one of the most important bioderived platform chemicals for synthesizing oxygen-functionalized organic molecules. These molecules include organic acids, aldehydes, and ketones such as glyceric acid (GLA), glyceraldehyde (GLD), and dihydroxyacetone (DHA). Various approaches such as thermocatalytic oxidation,5–10 catalytic decomposition11–13 and hydrodeoxygenation,14,15 and electrocatalytic oxidation16–26 have been recently considered to utilize and upgrade the excess glycerol.

The thermocatalytic oxidation of glycerol has been extensively studied experimentally over numerous metal catalysts,16–19 but this approach has several shortcomings. For example, the intensive activation of oxidants, low conversion, poor selectivity, and high operating temperature and pressure are problematic. The catalytic decomposition11–13 of glycerol, on the other hand, is hindered by slow reaction kinetics due to high activation barriers, and the catalytic hydrodeoxygenation14,15 is limited by high H2 pressures or flow rates. Both thermocatalytic and decomposition approaches produce mainly carbonaceous molecules with little to no oxygen content and fail to synthesize highly oxidized value-added chemicals. To improve selectivity toward the oxygen-rich products and to facilitate milder reaction conditions, the electrocatalytic oxidation of glycerol (EOG) has emerged as a highly competitive alternative.21,24,26 EOG can be efficiently operated at ambient reaction conditions eliminating the need for additional chemical oxidants such as oxygen or hydrogen peroxide. The electrocatalytic approach also allows finer control over activity and selectivity by modulating the applied electrode potential, electrolyte, and pH. In addition, coupling anodic EOG with the hydrogen evolution reaction (HER) taking place at the cathode makes hydrogen production a valuable side reaction.25,27,28

Given its numerous advantages, EOG has been studied on various metal electrocatalysts, including Au,21,24,26,29–30...
ClO₄⁻ conditions using a Na₂SO₄ electrolyte. Further oxidation of amounts of GLD have also been observed under neutral experiments have shown that Au electrocatalysts adsorb on the surface even in dilute (H)SO₄ solution. However, a recent joint experimental and theoretical study demonstrated that Au retains some activity even under acidic conditions in 0.1 M HClO₄. Perchlorate also adsorbs on the Au(111) surface although not as strongly as (hydrogen)sulfate which may explain the differences between the EOG activity in solutions containing ClO₄⁻ and (H)SO₄²⁻. Specifically, sulfates adsorb on the surface around 0.2 V vs RHE (henceforth referred to as V_RHE) in 1.0 M H₂SO₄ reaching a total coverage of 0.2 monolayer (ML) at 1.05 V_RHE while perchlorate adsors under more oxidative conditions starting at 0.4 V_RHE reaching a 0.15 ML coverage at 1.05 V_RHE in 0.1 M HClO₄.

The promising results for Au-catalyzed EOG in alkaline media have led to substantial research efforts devoted to understand its activity and selectivity. Gaining molecular understanding of EOG, however, has been difficult due to the high functionality of glycerol (GLY) and the complex reaction network with a variety of possible product molecules. Furthermore, solution pH substantially affects the conversion, activity, selectivity, and yield. In highly alkaline conditions, GLY oxidation is considered to take place via the primary hydroxyl group producing glyceraldehyde (GLD), which is very unstable under these conditions and quickly oxidizes to the first primary product, glyceraldehyde (GLA). Further oxidation products include, e.g., glycolic acid and formic acid. Under neutral and acidic conditions, Au electrocatalysts mainly produce dihydroxyacetone (DHA) via the oxidation of a secondary C group in GLY but minor amounts of GLD have also been observed under neutral conditions using a Na₂SO₄ electrolyte. Further oxidation of DHA under acidic conditions may lead to various products, such as, e.g., hydroxypruvic acid and mesoxalic acid. Production of DHA-derived species, however, depends on the electrochemical conditions.

Previous alcohol electro-oxidation experiments indicate that the catalytic performance of Au in an alkaline environment results from the formation of surface-adsorbed hydroxide species (referred to as Au(OH)₆₋; Au(OH)₄⁻ species are known to directly participate in various alcohol oxidation reactions by lowering the C–H and O–H bond dissociation barriers). The precise role of Au(OH)₆₋ on the reaction mechanism, thermodynamics, and kinetics is currently well understood for the oxidation of simple alcohols, such as methanol and ethanol. The effects of pH in more complex electro-oxidation reactions of multifunctional alcohols, like GLY, however, are less well understood. For instance, the role of aqueous OH⁻ ion or adsorbed OH on the EOG mechanism or kinetics under different electrochemical conditions has not been explored in atomic detail. The exact EOG mechanism remains controversial. Issues such as whether Au(OH)₆₋ catalyzes the dissociation of a C–H bond or an O–H bond, and whether primary or secondary O–H/C–H bonds are more reactive on the bare Au surface have remained unresolved. Experiments have shown that, under alkaline conditions close to or above the glycerol pKₐ (14.15), the dissociation of the primary O–H bond to glycerolate (GLD₁) and even the formation of GLD may be driven by aqueous OH⁻ ions. It remains unclear, however, whether the aqueous hydroxide or Au(OH)₆₋ is responsible for catalyzing the first O–H dissociation under less alkaline conditions where the concentration of GLD₁ decreases exponentially. Regardless of the mechanism that forms GLD₁, oxidation to GLA or further requires an electrocatalyst and either glycerolate or glycerol must adsorb onto the surface. In addition, chemical steps, such as the keto–enol tautomerisation between DHA and GLD which has been identified for thermochemical glycerol oxidation, may contribute to EOG under different pH conditions.

Though the thermodynamic origin of an electrocatalyst’s EOG activity and selectivity as a function of the pH and the electrode potential is partially understood from computations and experiments, the elementary kinetics has not been addressed even under acidic EOG conditions. Instead, the kinetics have been analyzed computationally only for thermocatalytic glycerol decomposition on close-packed transition metal surfaces such as Pt(111), Rh(111), Cu(111), and Ni(111). These results, however, are not directly transferable to EOG as the pH, electrode potential, and solvent effects have been omitted. Furthermore, experimental studies show that many thermocatalytic materials undergo surface oxidation and subsequent deactivation at relevant electrode potentials but such information for EOG active catalysts is still scarce.

In this work, we performed density functional theory (DFT) calculations to elucidate the initial EOG reaction mechanism on Au under different electrochemical reaction conditions and to understand how the activity and selectivity are modulated by the pH and electrode potentials. Specifically, the influence of the pH and potential on the EOG thermodynamics and kinetics was carefully analyzed. Pourbaix diagrams computed with the grand canonical ensemble DFT (GCE-DFT) are used to estimate the coverage of OH species on Au in oxidative environments as a function of pH and potential. The Pourbaix analysis is followed by a computational investigation of elementary reaction steps from GLY to dihydroxyacetone, glyceraldehyde, and glycric acid at different pH conditions. Our findings show that the presence of Au(OH)₆₋ species and keto–enol tautomerism are critical in explaining the experimentally observed pH-dependent EOG activity and selectivity on Au. In alkaline conditions, high activity and selectivity toward GLA stem from adsorbed OH whereas the absence of Au(OH)₆₋ leads to slow kinetics and DHA as the main product.

## COMPUTATIONAL DETAILS

All density functional theory (DFT) calculations were performed with the GPAW 1.5.2 software. The projector-augmented wave (PAW) formalism was employed to treat the frozen core electrons. The Kohn–Sham equations were solved using a real-space grid method with a grid spacing of 0.062.
0.18 Å, which has been demonstrated to yield converged energies for alcohols and oxides on Au. The exchange and correlation effects were described using the PBE0 functional with the Tkatchenko and Scheffler (TS09) dispersion correction. The solvent was accounted for by using a continuum solvent model for water as implemented in GPAW. For oxygen and hydrogen, standard cavity radii were used but a larger radius of 2.0 Å was used for Au based on our previous results. The details of the grand-canonical ensemble (GCE)-DFT calculations can be found in the Supporting Information.

The Au lattice constant was calculated to be 4.142 Å, which agrees well with the experimental value (4.065 Å). An Au(111) surface was selected to model the electrode surface because it is the most stable and abundant Au surface. This is beyond the focus of the present study. The Au(111) surface consists of a four-layer periodic 3 × 4 orthogonal unit cell. The coordinates of bottom two layers were fixed at their ideal bulk positions, while the top two layers were allowed to relax. The surface slabs were separated by a continuum solvent of 10 Å on both sides of the slab and a 4Å × 1 k-point mesh was used. Test calculations with (3× 2 × 1, 3× 3 × 1 and 4× 3 × 1) k-point samplings showed that adsorption energies of GLY and OH were underestimated by 0.05–0.09 eV, while (5× 4 × 1 and 5× 5 × 1) k-point samplings predicted the energies within 0.01 eV compared to a 4× 4 × 1 k-point sampling. The aqueous-phase species were treated in nonperiodic unit cells with 20 Å of implicit solvent in each direction. The geometry optimization was done using the BFGS method until the maximum residual force was below 0.05 eV Å⁻¹. First-order saddle points (transition states) on the potential energy surface (PES) were located using the climbing image nudged elastic band (CI-NEB) method, and the forces were converged below 0.05 eV Å⁻¹ except for the transition state of R9 on a 1/3 ML surface where the convergence criteria was relaxed to 0.15 eV Å⁻¹. The additional degrees of freedom introduced by the increased number of OH on the surface made convergence below 0.05 eV Å⁻¹ tedious. Intermediate images were created using the image-dependent pair potential (IDPP) interoliation scheme.

A vibrational analysis was carried out for all optimized minimum and transition state structures. The transition state structures were confirmed to have a single imaginary frequency. All free energies were calculated at NTP conditions and aqueous-phase free energies were obtained using the ideal-gas approximation. The free energies of surface-bound adsorbates were computed using hindered 2D rigid-rotor/translator approximation to account for the adsorbate free energies. The rotational and translational barriers were taken to be 0.05 and 0.1 eV, respectively, which are typical values for adsorbed organic molecules. Given the negligible pV term for adsorbed species, the Gibbs free energies are comparable to Helmholtz free energies (see the Supporting Information for further details).

**Computation of Adsorption, Activation, and Electrochemical Free Energies.** The adsorption free energies (ΔG_ads) of glycerol and its derivatives were computed as follows:

$$
\Delta G_{\text{ads}} = G(A^*) - G(A) - G(*)
$$

where G(A*), G(A), and G(*) represent the free energies of the surface-bound species, the isolated aqueous-phase species, and the bare surface, respectively.

The activation free energies (ΔG_act) for an elementary reaction step were determined as

$$
\Delta G_{\text{act}} = G_{\text{TS}} - G_{\text{RE}}
$$

where GTS and GRE are the free energies of optimized transition state and reactant structures, respectively. For some highly exergonic Au(OH)ads-catalyzed dehydrogenation reactions, transition states were impossible to locate as the reactants immediately converted to the corresponding product during structure optimization. We ensured that this behavior does not result from our computational setup but genuine features of the studied system as shown in the Supporting Information.

The EOG reaction free energies were computed using the computational hydrogen electrode (CHE) model, which treats the electrochemical potentials of proton and electron at equilibrium with (1/2)H₂ under standard conditions.

$$
\beta_{H^+} + \beta_{e^-} = 1/2 \mu_{H_2}
$$

We mainly used the reversible hydrogen electrode (RHE) scale, which can be obtained from standard hydrogen electrode (SHE) as $U_{\text{RHE}} = U_{\text{SHE}} + n_k T \ln 10 \times pH$. On the RHE scale, the potential-dependent free energies for the oxidation steps (ΔG(U_RHE)) within the CHE approximation are obtained as

$$
\Delta G(U_{\text{RHE}}) = \Delta G(U = 0) - n e U_{\text{RHE}}
$$

where n is the number of electrons transferred and e is elementary charge.

The EOG thermodynamics are discussed in terms of the standard equilibrium potential ($U_{eq}^{SHE}$) and the surface equilibrium potential ($U_{eq}^{surf}$) which use the solution and surface species as references, respectively. The $U_{eq}^S$ and $U_{eq}^{surf}$ values correspond to CHE-derived equilibrium potentials, where reactant and product species are equally stable. We also use the limiting potential ($U_{lim}$) to determine which applied electrode potential makes all elementary steps spontaneous or thermoneutral. These potentials are defined as

$$
U_{eq}^S(\text{RHE}) = \sum_i \Delta G_i(U = 0 \text{ vs RHE}) / n_{i,\text{tot}}
$$

$$
U_{eq}^{surf}(\text{RHE}) = \sum_i \Delta G_i^S(U = 0 \text{ vs RHE}) / n_{i,\text{tot}}
$$

$$
U_{lim} = \max_i \{\Delta G_i(U = 0 \text{ vs RHE})\}
$$

where index i denotes an electrochemical reaction step and * refers to an adsorbed species.

While the potential-dependent kinetics was not explicitly addressed, we confirmed that the Fermi levels are reasonably close to the experimentally relevant potential range of 0.2–1.1 V_RHE. The Fermi levels correspond to absolute electrode potentials and can be converted to the RHE scale through $U(\text{SHE}) = -e(E_p + 4.44 \text{ eV})$ using the implicit solvent model. The Fermi levels (electrode potentials vs RHE) are ~−4.8 eV (0.2 V at pH = 0 and 0.96 at pH = 13), −4.8 eV (0.2 V), and −4.9 eV (0.3 V at pH = 0 and 1.06 at pH = 13) for GLY adsorption, neutral/acidic NEB calculations, and alkaline NEB calculations, respectively. At other potentials, the barriers can be estimated using a Butler–Volmer-like equation,
dependence on the electrode potential. Calculations show that if the stabilization by explicit solvent interactions are accounted for, full OH coverage at pH = 13 is predicted to occur through the following mechanism:

$$\text{H}_2\text{O} (l) + * \rightleftharpoons \text{OH}^* + 1/2\text{H}_2$$

(6)

To model water oxidation and OH coverage as a function of the electrode potential and pH, we carried out GCE-DFT calculations, as detailed in the Supporting Information. The computational procedure was as follows: various OH coverages for a range of constant potentials were simulated using the SJM computational procedure was as follows: various OH coverages for a range of constant potentials were simulated using the SJM method to obtain surface grand free energies as a function of the electrode potential on the SHE scale. These values were then converted to RHE scale and the treatment of Duan and Henkelman was followed to explicitly address the pH effects. As derived in the Supporting Information, the OH adsorption grand free energies on the RHE scale are computed using

$$\Delta G_{\text{ads}}(U_{\text{RHE}}) = n \times \left[ \frac{1}{2} \mu_{\text{H}_2} - U_{\text{RHE}} \right] + \mu_{\text{OH}}(\text{RHE})$$

$$- [n\mu_{\text{H}_2} + \mu_{\text{Au}}(\text{RHE})]$$

(7)

where $\mu$ is the chemical potential of the given species. To obtain quantitatively accurate predictions for the OH adsorption energies, it is necessary to consider the deficiencies of the implicit solvent model applied. To that end, we also tested the effect of explicit solvent interactions by adding a correction of 0.53 eV for each adsorbed OH. This value was obtained by comparing OH adsorption energies calculated with an implicit solvent model and ab initio molecular dynamic simulations of an explicitly solvated Au(111) interface. The solvent correction, however, overestabilizes the OH adsorption. For example, if the stabilization by explicit solvent interactions is accounted for, full OH coverage at pH = 13 is predicted to take place at 0.76 V$_{\text{RHE}}$ (see Figure S2), which is much lower than seen experimentally (see Figure S2). It is possible that corrections for explicit solvent interactions depend on the surface coverage, but determining this relationship is outside the scope of the work presented here. We also considered the impact of the DFT functional on the OH adsorption energies and potentials as shown in the Supporting Information. Finally, we assessed the role of the adsorbed glycerol on the OH adsorption energy and coverage. Given the uncertainties related to the explicit solvent correction and the functional used, only the uncorrected values obtained directly from DFT are presented in the main text.

The electrosorption of species other than OH as a function of the potential was neglected. This is justified through the recently developed decoupled-CHE model, which uses the electrosorption valency ($\gamma$) and the amount of charge transfer ($\delta$) from the surface to the adsorbate to model electrosorption free energies as $\Delta G(U)_{\text{ads}} \propto \Delta G_{\text{ads}}(U = 0) + \gamma \delta$. Our calculations show that $\delta \approx 0$ for the adsorption of the EOG products (see Supporting Information) and, therefore, their adsorption energies are expected to display only weak dependence on the electrode potential.

### RESULTS

**Glycerol Adsorption on Au(111).** GLY exhibits various possible conformers; therefore, we considered the three most stable liquid-phase isomers identified in a previous extensive conformational analysis. In agreement with the previous study, we found conformer iii was the most stable (see Figure S3 and Table S2). Figure 1 displays the most stable GLY adsorption geometry, while all other adsorption structures and corresponding adsorption energies are given in Figure S4 and Table S3, respectively. The adsorption energy of the most stable conformer in water was calculated to be $-0.69$ eV ($\Delta G_{\text{ads}} = -0.29$ eV), which is $0.09$ eV more exergonic than the value computed in the gas phase. As shown in Table S3, van der Waals interactions are needed to make the GLY adsorption exothermic as they stabilize GLY adsorption by $\sim 0.7$ eV and are therefore used throughout the present work. The implicit solvent also greatly stabilizes GLY adsorption, but this effect may partially be overestimated by the deficiencies inherent to dielectric continuum models. The Bader charge analysis shows only a minor charge transfer (0.08 e) upon GLY adsorption on Au indicating that the electrode potential has only a small influence on GLY adsorption energy on Au.

**Surface Pourbaix Diagrams.** To address the pH effects in EOG, we start with surface Pourbaix diagrams for OH adsorption on Au(111) at 298 K. Figure 2 displays adsorption energies as a function of the electrode potential and pH at different coverages. The OH adsorption potentials as a function of pH are provided in Table S6. At 1/12 ML coverage, OH resides at a fcc hollow site but the adsorbed OH favors other sites with increasing coverage. For example, at 1/6 and 1/4 ML, bridge sites are preferred whereas top sites are occupied at 1/3, 1/2, and 1 ML.

At pH = 0, OH adsorption is thermodynamically unfavorable and the gold surface remains clean up to 1.35 V$_{\text{RHE}}$ at which point low OH coverage structures (1/12 and 1/6 ML) become stable. As the pH increases, 1/12 ML of OH becomes increasingly unstable, whereas the adsorption energy for 1/6 ML coverage is nearly independent of pH. These
The results in Figures 2 and S2 and Table S2 are again in good agreement with previous experimental and computational studies, reporting that OH adsorption at pH = 0 takes place around 0.5−1.5 $V_{\text{RHE}}$. While our OH adsorption potentials are slightly higher than those reported previously, the differences can be ascribed to the errors in OH adsorption on Au, which are around 0.1 eV and result from the use of the PBE functional or the flavor of the dispersion correction as discussed in the Supporting Information and shown in Figure S2 and Table S6. If the error due to the functional is accounted for, then OH adsorption under acidic condition becomes possible at 1.20 $V_{\text{RHE}}$. In addition, experimental measurements are often performed in solutions containing $SO_4^{2-}$ or $ClO_4^{-}$ species which also adsorb on gold surfaces and directly influence the OH adsorption/desorption potential under acidic and, to a lesser extent, neutral conditions by blocking possible OH adsorption sites.

OH adsorption at coverages higher than 1/4 ML becomes thermodynamically more favorable with increasing pH. This type of pH dependency, known as a non-Nernstian shift, results from shifts in the zero charge potential of the interface as a function of coverage and the surface dipole. Figure 2 and Table S6 show that the 1/3 ML OH structure is the most stable configuration under typical alkaline conditions of pH = 13 and has an adsorption potential of 1.29 $V_{\text{RHE}}$. The 1/2 ML OH coverage at pH = 13 is almost equally stable and becomes thermodynamically stable at 1.34 $V_{\text{RHE}}$. If errors in the adsorption energies caused by the DFT functional are accounted for, both 1/3 ML and 1/2 ML coverages become stable around 1.15 $V_{\text{RHE}}$, as shown in Figure S2 and Table S6. The results in Figures 2 and S2 and Table S2 are again in good agreement with the experimental results under alkaline conditions showing that OH adsorption starts around 0.6 $V_{\text{RHE}}$ and reaches a maximum coverage of 0.4−0.5 ML around 1.3 $V_{\text{RHE}}$. While our predictions on stable OH coverages are consistent with experiments, the adsorption potentials are again slightly higher than those observed experimentally and this is attributed to DFT errors, surface reconstructions as well as the presence of ions in experiments.

Finally, we addressed the effect of glycerol adsorption on OH adsorption energies. A GLY coverage of 1/12 ML enhances OH adsorption by ~0.15 e and ~0.05 eV at 1/12 and 1/6 ML OH coverages, respectively. The glycerol−OH Pourbaix diagram (see Figure S15) shows the coadsorbed OH−GLY becoming stable around 0.7 $V_{\text{RHE}}$. Glycerol coadsorption is therefore expected to facilitate OH adsorption allowing the oxidation reaction to begin at slightly lower potentials than predicted based on OH adsorption alone. This suggestion is supported by the slightly shifted oxidation peak of simpler alcohols.

The onset potential of EOG on Au at pH = 13 is ~1.0 $V_{\text{RHE}}$, and all the activity is lost after ~1.4 $V_{\text{RHE}}$. We have not explored the surface oxide formation because it starts at 1.54 $V_{\text{RHE}}$ according to an extensive experimental and computational study. These observations indicate that alkaline EOG activity on Au is closely related to the formation of surface hydroxides in the presence of GLY, which may take place at experimentally relevant EOG potentials of 0.8−1.4 $V_{\text{RHE}}$.

Overall, the computed Pourbaix diagrams and OH adsorption energies show that OH adsorption exhibits a non-Nernstian shift on the RHE scale. Under acidic conditions, only low OH surface coverages are likely to be observed in the potential region relevant for EOG. Under alkaline conditions a moderate OH coverage between 1/3 and 1/2 ML is predicted to exist under EOG potentials. Glycerol stabilizes OH adsorption indicating that both GLY and OH are simultaneously present on the surface at the experimentally relevant EOG conditions. Computational models for Au-catalyzed alkaline EOG should therefore explicitly account for the influence of the OH coverage.

Electrocatalytic Oxidation of Glycerol under Neutral and Acidic Conditions. We have considered four competing pathways producing either dihydroxyacetone (DHA) or glyceraldehyde (GLD). DHA is the major EOG product on Au under acidic or neutral conditions but has low yields, whereas GLD formation has only been observed under neutral conditions and at high potential. Figure 3 summarizes the elementary mechanism and energetics of the reaction pathways considered for EOG on Au(111): RS1 and RS2 lead to DHA while RS3 and RS4 form GLD. RS1 starts with the oxidation of the secondary OH group followed by the oxidation of the secondary CH group to produce DHA, while along the RS2 reaction pathway, the elementary steps take place in the reverse order. Similarly, GLD production goes through a two-step oxidation process but this time through the primary CH2OH fragment via pathways RS3 and RS4. According to our Pourbaix diagrams, the Au(111) surface is either free of OH species or has a low OH coverage at relevant electrochemical potentials under acidic and neutral reaction conditions. We model the acidic and neutral conditions on the bare Au surface but acknowledge that at highly oxidative potentials OH might be present on the surface. We also note that experimental studies under acidic or neutral conditions are performed in the presence of specifically adsorbing anions but these are not considered in the present study.

Acidic and Neutral EOG Thermodynamics. For the thermodynamic analysis of EOG, we carried out a careful screening of intermediate and product adsorption structures by considering various configurations and active sites. Stable adsorption geometries and energies are presented in Figure S5.
and Table S4, respectively. Figure 3 summarizes the main results and a detailed description of the thermodynamic free energy surfaces at 298 K along the RS1-RS4 pathways can be found in Figure S5. After GLY adsorption onto the electrode, the first bond breaking steps along all the pathways are endergonic. Figure 3 shows that the oxidation of secondary and primary C groups (RS2 and RS4) is thermodynamically more favorable than the oxidation of secondary and primary OH groups (RS1 and RS3). Furthermore, H elimination from the secondary carbon (GLY* = DHA2*) is more favorable than the abstraction of the primary H (GLY* = GLD2*).

Along RS2, the second elementary step is a H elimination from the secondary OH group leading to DHA formation followed by its desorption. Overall, the thermodynamic analysis indicates that on Au, EOG produces mainly DHA at acidic and neutral pH conditions via RS2 pathway in agreement with a previous computational study.22

Figure 4 presents potential-dependent thermodynamics for the favored RS2 and RS4 pathways at pH = 0 and at different potentials corresponding to the computed $U = 0 \, \text{V}$, $U_{eq}$, $U_{eq, surf}$, and $U_{L}$ values. The last thermodynamic steps, DHA* = DHA(aq) and GLD* = GLD(aq), removing the products from Au(111) into the liquid phase, are chemical steps and therefore independent of the applied potential. Figure 4 clearly shows that DHA production is thermodynamically more facile with a limiting potential of 0.17 V_{RHE} than GLD formation for which the limiting potential is 0.60 V_{RHE}. These findings are in line with previously reported values of 0.39 (DHA) and 0.60 (GLD) V_{RHE} computed in vacuum and at pH = 0, where the RHE and SHE scales are identical.22 In the pH range 1−4, the limiting potential for GLY to DHA oxidation varies from 0.23 V_{RHE} to 0.41 V_{RHE} and for GLY to GLD transformation from 0.66 V_{RHE} to 0.84 V_{RHE}. This further supports our finding that DHA formation is thermodynamically favored via the RS2 pathway in acidic and neutral media.

**Acidic and Neutral EOG Kinetics.** The acidic and neutral EOG kinetics toward DHA and GLD along four competing pathways was explored. Figure 3 provides the computed activation barriers for each elementary step, while the complete potential free energy surfaces and transition state structures are provided in Figures S6 and S9, respectively. We find that, regardless of the product molecule, GLY deprotonation occurs via the C−H bond cleavage. The deprotonation of the secondary C, leading to DHA2, has a barrier of 0.98 eV, which is ~0.3 eV lower than the barrier for the deprotonation of the primary C leading to GLD2. The subsequent deprotonation

![Figure 3. Reaction mechanism of glycerol (GLY) oxidation to dihydroxyacetone (DHA) and glyceraldehyde (GLD) in acidic/neutral environment and NTP ensemble conditions. Rn beneath arrows denotes a reaction number along the RS1−RS4 pathways, and the quantities provided in the parentheses are activation free energy/reaction free energy in eV.](image)

![Figure 4. Potential-dependent (pH = 0) oxidation thermodynamics for GLY conversion to (a) dihydroxyacetone (DHA) and (b) glyceraldehyde (GLD) on the Au(111) surface. Free energies are shown for zero potential, the surface equilibrium potential, $U_{eq}$, the standard equilibrium potential, $U_{eq, surf}$, and the limiting potential, $U_{L}$, in V_{RHE}, respectively.](image)
barriers are lower than those observed for the first deprotonation reactions. These results show that RS2 is also kinetically the most favorable pathway but it has a high kinetic barrier, $\sim 1$ eV, for the first oxidation reaction. Both kinetic and thermodynamic perspectives show that the first proton and electron transfer reactions along RS2 and RS4 are likely to be the rate-determining steps for EOG in acidic and neutral media. This finding agrees with experimental results, where the Tafel slope of $\sim 120$ mV dec$^{-1}$ on the clean Au surface was observed and this high value typically indicates that the first electron transfer is the rate-determining step. Current densities in acidic/neutral media, however, are expected to be small due to the high activation barriers.

**Electrocatalytic Oxidation of Glycerol under Alkaline Conditions.** In alkaline media, GLA has been identified as the main product or reaction intermediate toward more oxygenated species but the formation of DHA cannot be ruled out a priori based on current experimental data. Figure 5 summarizes the complete reaction network for all intermediates down to glyceric acid (GLA).

**Alkaline EOG Thermodynamics.** The alkaline conditions on Au(111) are represented by explicitly adding OH groups on the surface. As shown in the Pourbaix diagrams (see Figure 2), the Au(111) surface has $\sim 1/3$ to $1/2$ ML OH coverage under highly alkaline conditions for a wide range of potentials. Glycerol adsorption also enhances OH adsorption. We also note that under alkaline conditions, no specifically adsorbing anions other than OH$^-$ are used experimentally. The computational model for Au-catalyzed alkaline EOG must therefore explicitly take into account the influence of coadsorbed OH. To that end, two OH groups, corresponding to 1/6 ML coverage, were added to the Au(111) surface. The lower 1/6 ML OH coverage was applied to reduce the possible spatial variations of OH around the glycerol. This coverage also represents a minimal model where one OH abstracts a proton from the organic reactant and converts it to a water molecule, while the other OH remains on the surface and stabilizes the reacting species throughout the reaction. To test that the OH groups on the 1/6 ML surface are necessary and sufficient to reproduce alkaline conditions, we computed the R9 reaction energetics for 1/12 and 1/3 ML surfaces (see Figure S8). For the 1/12 ML surface, the reaction energy is 1.05 eV and the reaction barrier is 1.29 eV. The barrier is not significantly lower than that on the bare surface demonstrating that at least a 1/6 ML OH coverage is necessary to mimic alkaline conditions. The reaction energy and barrier for the 1/3 ML surface are $-0.71$ and 0.68 eV, respectively. The results from the 1/3 ML surface and the 1/6 ML surface are comparable indicating that 1/6 ML OH coverage is sufficient to capture most effects observed under alkaline conditions and to study the effect of Au(OH)$_{ads}$ on EOG.

The alkaline reaction mechanism and thermodynamics are summarized in Figure 5 and a more complete thermodynamic profile is presented in Figure S9. The thermodynamics to regenerate the adsorbed OH is not shown in these figures but can be inferred from the data in Figure 2. We have considered GLY oxidation to DHA and GLD and further to GLA, as GLD is unstable under these reaction conditions. The reaction thermodynamics in Figures 5 and S8 for EOG intermediates and the energies of adsorbed OH species were computed separately in different unit cells, i.e., infinitely separated from each other. This approach is necessary because in the presence of adsorbed OH in the unit cell some EOG intermediates are unstable and, during geometry optimization, they immediately donate a hydrogen atom to the adsorbed OH group preventing the calculation of elementary thermodynamics. The "infinite-
separation” assumption is similar to low-coverage assumption often utilized in mean-field microkinetic modeling. In general, the majority of elementary steps are exothermic or at least thermoneutral in alkaline media. We found that the RS2 and RS4 pathways, where the proton is first eliminated from the carbon, are thermodynamically more favorable than removing the proton from the OH group of GLY. Similar behavior was also observed in acidic and neutral media but under alkaline conditions, surface OH groups actively participate to abstract the protons and produce water. The thermodynamic analysis alone does not allow conclusions on the activity and product selectivity; an analysis of the reaction kinetics is therefore required.

**Alkaline EOG Reaction Kinetics.** The natural next step is to address reaction kinetics and compute activation free energies, which are shown in Figure 5. Kinetically feasible DHA and GLD formation is obtained along the RS1 and RS3 pathways, where H is first removed from OH and then from C. For both steps, the barriers are smaller than 0.1 eV. Along RS2 and RS4, H abstraction takes place in the reverse order, but the first deprotonation free energy barrier is over 0.5 eV. Overall, the reaction barriers in alkaline media are significantly lower than those found in acidic or neutral conditions. We attribute this difference to the extremely effective activation of O−H bonds by the surface-bound OH groups, which has also been observed for ethanol oxidation on Au(111). The Au(OH)ads− induced low barriers also explain the experimentally observed high activity of Au-catalyzed alkaline EOG.20−29

We found that the formation of GLA from GLD is highly exergonic and GLA acts as a thermodynamic sink driving the reaction toward further oxidation if the formation of GLD is possible. GLD can easily oxidize to GLA via a nearly barrierless OH group substitution to GLD (R7) followed by a proton abstraction from the terminal C (R8) which has an activation energy of 0.27 eV. A similar mechanism has been previously proposed based on cyclic voltammetry and online electrochemical mass spectrometry experiments. For comparison, we also studied the GLD to GLA oxidation on the empty Au(111) sites not covered with an adsorbed OH. The reaction network and the corresponding energy values are shown in Figure S7 and Table S5, respectively. Interestingly, on the empty Au(111) sites, step R8 is barrierless, which indicates that maximal alkaline EOG activity is achieved when some elementary steps are catalyzed by OH groups and others by empty Au surface sites. Combinations of OH-covered and empty surface sites are possible with the modest 1/12 ML OH coverage on the Au(111) surface. Combinations of OH-covered and empty surface sites are found to be stable under different pH and potential conditions as shown in Figure 2.

To address the EOG selectivity, the competitive pathways toward DHA and GLD were studied under alkaline conditions. We found that DHA can be easily generated via the RS1 pathway, which is thermodynamically and kinetically feasible in the presence of surface-bound OH groups (see Figure 5 and Table S5) having a reaction energy of −1.86 eV and a kinetic barrier below 0.1 eV. Forming DHA is therefore very competitive with GLD formation. This means that it is not possible to discern selectivity between these two species in alkaline media and a mixture should be observed in experiments. Experiments, however, have demonstrated that GLA is the sole primary product in Au-catalyzed alkaline EOG36,19,24 suggesting that there is a mechanism for converting DHA to GLD, which then further reacts to form the stable oxidized product GLA. One such pathway is provided by the keto−enol tautomerization between DHA and GLD displayed in Figure S11. To address this possibility, we computed the reaction free energy for this step and found the \( \Delta G \) to be 0.01 eV for DHA \( = \) GLD in the presence of 1/6 ML OH. This indicates that DHA and GLD can be easily interconverted under alkaline conditions as also suggested for thermocatalytic conversion of GLY.34,95

**DISCUSSION**

The present DFT study provides new atomistic insight into the reaction mechanism and pH dependence of GLY electro-oxidation on Au(111) at experimentally relevant potentials. Our detailed analysis of reaction thermodynamics and kinetics demonstrates that it is necessary to explicitly take Au-adsorbed OH species into account when constructing comprehensive computational models for EOG and possibly other electro-oxidation reactions. This is particularly important for modeling oxidation reactions in alkaline media, where surface hydroxides or, at higher potentials, oxides are present on a catalyst surface and participate in (electro)catalytic transformations. Interestingly, our results also highlight that chemical steps such as keto−enol tautomerism can play a pivotal role in determining the reaction mechanism and selectivity of electrocatalytic reactions under different reaction conditions.

The first step toward elucidating experimentally observed pH sensitivity of EOG is to understand the state of the catalyst surface under operating conditions. To achieve this, we constructed Pourbaix diagrams, which demonstrate that OH coverage on the Au(111) surface depends explicitly on the pH in the RHE scale. Under acidic conditions (pH = 1), the surface is clean until \( > \)1.3 V_RHE, at which point a 1/12 ML OH coverage becomes stable. This potential coincides well with the onset potential for acidic EOG on gold.22 Under alkaline conditions (pH = 14), 1/3−1/2 ML OH becomes stable at lower potentials, around \( > \)1.3 V_RHE, and is very close to the observed alkaline EOG onset potential.19 Under neutral conditions (pH = 7), our simulations predict that 1/12, 1/6, and 1/3 ML OH coverages are the most favorable OH adsorption structures becoming stable at potentials \( > \)1.3 V_RHE again in good agreement with the EOG onset potential.19 We also verified that GLY adsorption is slightly enhanced by the presence Au(OH)ads− suggesting that hydroxyl adsorption is likely to be accompanied by GLY adsorption and that EOG starts at slightly less oxidizing potentials than required to oxidize Au without GLY. The potential and pH range for GLY and OH to be simultaneously adsorbed on Au(111) sets the conditions where both species available on the surface. The OH adsorption potentials, however, are similar under varying pH conditions and the OH coverage alone cannot be the sole reason for the experimentally observed pH-dependent EOG activity and selectivity. As discussed below, in alkaline EOG experiments OH− is the only anion present in the electrolyte whereas acidic and neutral experiments are carried in the presence of sulfate or perchlorate anions which can significantly influence EOG.

Surface bound OH groups make all oxidation reactions considered highly exergonic or at least thermoneutral (see Figures 5 and S8) explaining why Au-catalyzed EOG is so favorable under alkaline conditions similar to the electro-oxidation of simple alcohols.49,50 Our results show that alkaline surface-catalyzed EOG starts with H-abstraction from the OH group by a surface-bound hydroxide in agreement with the vast majority of experiments.22,19,24 The surface bound OH
Figure 6. Optimal EOG reaction pathway in alkaline conditions on the Au(111) surface. The magenta arrows indicate base-catalyzed (aqueous OH−) reactions producing solvated DHA1− and GLD1− species. The blue arrows indicate the reaction steps assisted by an Au(OH)ads active site whereas the green arrow denotes a reaction on a Au active site.

species mediate the oxidation of primary or secondary C−OH groups of GLY as they provide a basic site to remove the slightly acidic proton from the alcohol functional group. This is reflected in the very small activation free energies for the pathways leading to either DHA, GLD, or GLA. The formation and presence of Au(OH)ads is therefore an integral part of the EOG chemistry substantially modifying the kinetics and thermodynamics. Yet, the formation of these hydroxide species is spontaneous only at relatively oxidizing potentials above ∼1 $V_{RHE}$ as shown by the Pourbaix diagram for GLY (Figure S15) and surface hydroxides in Figure 2. Hence, our explanation for the fairly high onset potentials observed experimentally for alkaline EOG on Au18,19 is that the increase in activity coincides with GLY adsorption and the formation of Au(OH)ads making EOG feasible.

The results also show that under alkaline conditions, the Au(111) surface has moderate OH coverage (1/3−1/2 ML) and contains two types of reaction sites, i.e., Au(OH)ads and empty Au, both of which are needed for GLY conversion. The majority of steps from GLY to GLA along the reaction pathway RS3 proceed via the OH-assisted route except the last step from GLA1 to GLA, which is thermodynamically and kinetically preferred on an empty Au site rather than a Au(OH)ads site. The surface-catalyzed alkaline EOG activity can thus be optimized if two different active sites, Au and Au(OH)ads are present. It can therefore be concluded that under alkaline conditions the optimal EOG reaction on Au operates via a two-site mechanism as previously suggested for methanol oxidation.96 Such a dual-site mechanism is also supported by experimental5,18 and computational5,12,57 studies of thermocatalytic metal-catalyzed alcohol oxidation in alkaline conditions. The dual-site mechanism has also been proposed for the thermocatalytic production of either DHA or GLD over Pt but in this case the generation of Pt−OH sites is unfavorable.57

The combined thermodynamic, kinetic, and mechanistic analyses resolve some open questions regarding the Au-catalyzed EOG mechanism. The computational results suggest that, in alkaline conditions, the oxidation of GLY begins with the abstraction of hydrogen from an O−H bond followed by subsequent deprotonation of C−H. Both deprotonation reactions are found to be easily mediated by either surface hydroxides or gold atoms. An alternative pathway supported by experiments18 is that solution-phase OH− first deprotonates GLY to GLD1 in solution followed by GLD1 (glycerolate) adsorption on the surface. For these reactions, a Hammett relationship was demonstrated between the alcohol reactivities and their pKa values18 such that a lower pKa value corresponds to higher alcohol oxidation reactivity. This suggests the solution-phase OH− ions may play a greater role for the overall activity/reactivity than the Au(OH)ads intermediates. It is also possible the local solution pH is even higher near the electrode in the (outer) Helmholtz layer such that GLY can be efficiently deprotonated. As the charged glycerolate adsorbs more strongly than the neutral GLY,18 higher EOG activity under alkaline conditions can partially be attributed to more exergonic adsorption of the reactant. The stronger adsorption was also confirmed as the computed GLD1 adsorption energy is −1.35 eV which is ∼0.6 eV stronger than GLY adsorption. Therefore, we agree with experiments that the GLY oxidation to GLD1 is most likely catalyzed by aqueous OH−, i.e., a base-catalyzed reaction. While the presence of solvent-phase OH− can induce stronger adsorption, base (OH−)− influenced catalysis can only occur when the (local) pH is close to the glycerol pKa at 14.15. In contrast, adsorbed OH species can participate in EOG even under more acidic conditions. Furthermore, abstracting a second proton from GLD1 would result in an anionic intermediate and GLD1 likely has a very high pKa.57 The Au or Au(OH)ads under alkaline conditions are therefore needed to accomplish the conversion of GLD1 to GLD which proceeds easily under alkaline conditions. Further oxidation of GLD to GLA may proceed either through Au(OH)ads on the surface (Figure 2) or solvated OH− base catalysis in the presence of oxygen.18,19 While experimental data led to the conclusion that base catalysis is the dominant mechanism,18,19 Au(OH)ads-catalyzed oxidation of GLD to GLA on the surface is both kinetically and thermodynamically facile. GLD desorption is an endergonic process (see Figure 4) and has a higher barrier than GLD → GLA1 oxidation in the presence of adsorbed OH; therefore, the formation of GLA is expected to proceed through surface catalysis.

Based on our computational results and previous experimental studies,96 we propose the following mechanism where base and surface catalysis act cooperatively under alkaline conditions as shown in Figure 6. (1) The alkaline solution promotes glycerolate (GLD1) formation which adsorbs on the surface more strongly than glycerol. (2) Efficient conversion of GLD1 → GLD requires that Au(OH)ads participates in the process. (3) Further oxidation of GLD to GLA1 also takes place on the surface through Au(OH)ads. (4) GLA1 → GLA occurs on the pure Au sites. Steps 1 and 2 are the same as previously proposed based on experiments while steps 3 and 4 differ.18,19 Our mechanism also differs from the fully surface-catalyzed EOG mechanism recently suggested.56 The proposed alkaline EOG pathway on gold consists of cooperative base-
surface catalysis where some steps are catalyzed by aqueous OH\(^{-}\), Au(OH)\(_{ads}\) empty Au sites.

In the absence of Au(OH)\(_{ads}\) EOG proceeds differently, taking place on the Au sites or in the presence of low OH coverage at high oxidation potentials. According to the thermodynamic and kinetic analyses, DHA is the main product in agreement with previous calculations\(^{35}\) and experiments at low oxidation potentials and acidic conditions,\(^{22}\) but the rate/current density is expected to be small due to the relatively high kinetic barriers. Our results show that for acidic EOG at low oxidation potentials (below 1.3 V\(_{RHE}\) at pH = 1), DHA is produced via secondary C—H elimination in agreement with a previous study.\(^{22}\) Experimentally, a marked increase in current densities was observed at oxidizing potentials of 1.2—1.5 V\(_{RHE}\) at pH = 1 but could not be rationalized.\(^{37}\) We ascribe this to the presence of OH on the surface under these conditions (see Figure 2), which significantly increases EOG activity as discussed above for the alkaline mechanism. In acidic solutions, however, the base catalysis component is absent and we propose that EOG is fully surface catalyzed in accordance with present mechanistic understanding.\(^{54}\) Furthermore, acidic EOG seems sensitive to the nature of the counterion, as EOG proceeds only in HClO\(_4\) thermore, acidic EOG seems sensitive to the nature of the counterion, as EOG proceeds only in HClO\(_4\) but not in H\(_2\)SO\(_4\).\(^{19}\) This sensitivity is likely related to the specific adsorption of SO\(_4^{2-}\) affecting Au(OH)\(_{ads}\) formation:\(^{30}\) Au surfaces have long been believed to be inactive toward acidic EOG,\(^{16,19}\) which might be due to SO\(_4^{2-}\) adsorption as well as low EOG activity and selectivity resulting from the high reaction barriers in the absence of proton acceptors, such as hydroxides, on the surface. This hypothesis can be tested experimentally by doping Au with more basic metals or by decorating Au with basic oxides\(^{7,97—101}\) or using SO\(_4^{2-}\) or ClO\(_4^{-}\) free solutions.

Our results predict that a wide range of OH coverages are stable at potentials above ~1.35 V\(_{RHE}\) at pH = 7. Given the role of OH in facilitating EOG, our calculations suggest the current density under neutral conditions is negligible below 1.35 V\(_{RHE}\) but should increase above this potential. Our calculated adsorption potentials for higher OH surface coverages expected under alkaline conditions are aligned with the experimentally observed decrease in EOG onset potential as the pH increases.\(^{19,102}\) The prediction of higher EOG onset potentials below 1.35 V\(_{RHE}\) is also consistent with the low current density observed under neutral conditions. The 1/6 and 1/3 ML OH coverages are therefore expected to catalyze GLD formation via primary O—H elimination at high potentials (>1.35 V\(_{RHE}\)) in neutral media following the same mechanism observed for alkaline EOG. This reasoning is consistent with the experimental suggestion\(^{19}\) that EOG follows similar pathways under neutral and alkaline conditions. Our results, however, cannot fully explain the drastic difference in EOG activity between neutral and alkaline conditions that is experimentally observed above OH adsorption potentials. As we have shown that adsorbed hydroxides lower the barriers for EOG, to explain this kinetic difference, we suspect the low reaction rates or currents are due to the SO\(_4^{2-}\) and ClO\(_4^{-}\) anions used in neutral EOG experiments.\(^{19,102}\) Both anions are known to specifically adsorb on gold surfaces between 0.2 and 1.05 V\(_{RHE}\) and to reach 0.15—0.2 ML surface coverages.\(^{40,41}\) The low currents can be explained by combining the fact that SO\(_4^{2-}\) is adsorbed on the surface at potentials up to 1.2 V\(_{RHE}\) at pH = 0, after which Au surface oxidation begins,\(^{40}\) with the anions’ suspected role in blocking GLY or GLD adsorption.\(^{102}\)

Surface-enhanced IR absorption spectroscopy measurements have also shown that Au(OH)\(_{ads}\) and adsorbed SO\(_4^{2-}\) can coexist up to 1.5 V\(_{RHE}\) under neutral conditions which coincides well with our calculated OH adsorption potential at pH = 7 and the experimental onset potential around 1.2—1.3 V\(_{RHE}\). We therefore suggest the small non-Nernstian shifts in the OH coverage combined with specific anion adsorption are the reasons for low EOG activity under neutral conditions.

Verification of this suggestion calls for computational studies of EOG for coadsorbed OH+ sulfate/perchlorate structures.

In addition to pH effects influencing base catalysis (through aqueous OH\(^{-}\)) and surface catalysis (through Au(OH)\(_{ads}\)), the pH was found to affect EOG selectivity via keto—enol tautomerism between DHA and GLD. The computed reaction free energy demonstrates that DHA-GLD tautomerism is thermoneutral under alkaline conditions and offers an alternative pathway to form GLD from DHA. Once formed, GLD can easily oxidize to highly stable GLA, which acts as a thermodynamic sink for EOG as shown in Figures 5 and 8. This observation explains the experimentally observed activity and selectivity toward GLA and absence of DHA under alkaline conditions. Interestingly, the tautomerization is thermodynamically less favorable under acidic conditions on the bare Au surface since \(\Delta G\) is 0.24 eV (see Figure S11). Alkaline conditions also enhance the tautomerism kinetics as the adsorbed OH species can cleave the C—H bond while a water molecule or another EOG intermediate simultaneously donates a proton to form the enol intermediate (see Figure S11).\(^{103}\) GLD formation directly from GLY in acidic media is less favorable than DHA formation and the absence of efficient hydrogen acceptors would make the reaction kinetically sluggish. As a result, GLD cannot form easily in acidic environments and Au-catalyzed EOG should lead only to DHA and DHA-derived products as supported by previous experimental and computational studies.\(^{22}\) Overall, our findings on the tautomerism in EOG agree with experimental results on thermal GLY conversion,\(^{94,95}\) where the pivotal role of the DHA-GLD keto—enol tautomerism for pH-dependent selectivity has been reported at high pH.

After obtaining robust mechanistic understanding of EOG, we briefly address how this could be utilized in catalyst screening. We attempted to establish linear scaling relations between adsorption energies of initial and final states of elementary steps as well as the Bronsted–Evans–Polanyi (BEP) relationships between the activation and reaction energies. The correlations obtained are presented in Figure S13. For EOG on the clean Au(111) surface, mimicking acidic and neutral conditions, excellent scaling and BEP relationships were obtained with the \(R^2\) value of ~0.96 (see Figure S11a, b). This highlights that one descriptor, the reaction energy of an elementary step, can successfully determine EOG reaction barriers. Unfortunately, on the hydroxylated Au(111) surface neither adsorption nor activation energies are correlated with reaction energies (see Figure S11c, d). This indicates that H\(_2\)O or/and OH configurations close to a particular glycerol derivative influence the reaction kinetics and thermodynamics through direct adsorbate—adsorbate interactions, which are absent from clean surfaces or mean-field models. As previously proposed,\(^{104}\) a possible approach to explore the role of these coverage effects would be to construct OH-coverage Pourbaix diagrams to identify the stable surface phase for each adsorbate separately and then use these structures for determining reaction kinetics and thermodynamics. Regardless, alkaline
conditions require more comprehensive computational models, considering the role of OH groups in both solution and on the surface, or alternative mechanistic pathways such as keto–enol tautomerism, to describe the reaction environment and examine EOG reaction pathways. Furthermore, the effect of anion/OH coadsorption should be included in the models to address the electrolyte and pH effects. We anticipate that such species and reactions should be more thoroughly taken into account when addressing the electrocatalytic conversions of complex molecules under reaction conditions.

## CONCLUSIONS

We performed an extensive computational study to explain the experimentally observed potential and pH dependency of Au-catalyzed glycerol electro-oxidation. Pourbaix diagrams were constructed to analyze the variation of adsorbed OH groups as a function of the electrode potential and solution pH. Our calculations have shown a non-Nernstian shift for 1/3–1/2 ML OH coverage and increased EOG activity with OH on the surface which compares well with the activity observed on Au surfaces under alkaline conditions. Conversely, OH adsorbs at slightly higher potentials under acidic conditions and the clean surface does not favor EOG which also agrees with experiments. Although our calculations indicate similar activity between neutral and alkaline conditions above OH adsorption potentials, previous experiments suggest typical neutral solution electrolytes, sulfate and perchlorate, obstruct glycerol adsorption. Therefore, at experimentally relevant potentials, the Au(111) surface exists with a modest OH coverage without any specifically adsorbed anions under alkaline conditions whereas OH±sulfate/perchlorate coadsorbed structures or a lower OH coverage may exist under acidic conditions.

EOG thermodynamics and kinetics were investigated on both the pristine and OH-covered Au surfaces, mimicking acidic or low potential and alkaline or high potential conditions, respectively. We found that under acidic conditions glycerol conversion to dihydroxyacetone is both kinetically and thermodynamically more favorable than the conversion to glyceraldehyde, which agrees with the experimentally observed selectivity. Poor EOG activity of Au reported under acidic conditions, however, results from the kinetic hindrance of dihydroxyacetone formation. Under alkaline conditions, the presence of OH groups makes the glyceraldehyde formation and further oxidation to glyceric acid feasible. The reaction barriers on the OH-covered Au(111) surface are substantially lower than those on the pristine surface explaining the higher activity under alkaline conditions. The experimentally observed selectivity toward glyceric acid in alkaline media is attributed to fast reaction kinetics and favorable thermodynamics of glyceraldehyde oxidation to glyceric acid. Furthermore, our results support the existence of a dual active site under alkaline conditions and at low OH coverage allowing some deprotonation steps to be Au(OH)ads catalyzed while others are surface (Au) catalyzed. We also show that the chemical keto–enol tautomerism between dihydroxyacetone and glyceraldehyde is pivotal in determining the electrocatalytic selectivity under alkaline conditions. This provides a pathway to convert dihydroxyacetone to glyceric acid and explains why dihydroxyacetone is observed at high pH. Under acidic conditions, the keto–enol tautomerism is thermodynamically unfavorable and therefore dihydroxyacetone cannot be easily transformed to glyceraldehyde or glyceric acid. Altogether, we have provided consistent mechanistic understanding for the experimentally observed EOG activity and selectivity on Au, but this has required explicit consideration of pH and potential effects on OH coverage, thermodynamics, kinetics, and the reaction mechanism as well as invoking the experimentally verified coadsorption of OH and perchlorate/sulfate under acidic and neutral conditions.

Beyond the Au-catalyzed EOG, our results combined with previous experiments highlight that the effect of pH, OH surface coverage, and the electrolyte must be explicitly included in computational studies of electrocatalytic oxidation reactions. The presence of adsorbed OH qualitatively and quantitatively changes the elementary thermodynamics, kinetics, and reaction mechanisms. The experimental results can only be explained by explicitly accounting for the effect of reaction conditions. This conclusion has potentially wide implications on future computational studies of electrocatalytic activity and selectivity. In particular, alkaline oxidation reactions are likely to be explicitly dependent on the pH and OH-surface coverage and they cannot be fully understood with overly simplified reaction models, thermodynamics alone, or linear free energy relationships, therefore calling for more comprehensive computational approaches.
