Abstract
Mutations in the sodium-activated potassium channel gene KCNT1 have been associated with nonlesional sleep-related hypermotor epilepsy (SHE). We report the co-occurrence of mild malformation of cortical development (mMCD) and KCNT1 mutations in four patients with SHE. Focal cortical dysplasia type I was neuropathologically diagnosed after epilepsy surgery in three unrelated MRI-negative patients, periventricular nodular heterotopia was detected in one patient by MRI. Our findings suggest that KCNT1 epileptogenicity may result not only from dysregulated excitability by controlling Na+K+ transport, but also from mMCD. Therefore, pathogenic variants in KCNT1 may encompass both lesional and nonlesional epilepsies.

Introduction
Sleep-related hypermotor epilepsy (SHE), formerly known as nocturnal frontal lobe epilepsy, is characterized by focal seizures with various motor manifestations occurring during sleep.1 Autosomal dominant forms of SHE (ADSHE) have been associated with mutations of genes encoding sub-units of the neuronal acetylcholine receptor (CHRNA4, CHRN2, CHRNA2) or proteins of the mTORC1/GATOR1 complex (DEPDC5, NPRL2/3). Heterozygous missense mutations in KCNT1 were reported in a severe form of ADSHE with normal MRI, drug-resistant seizures, intellectual
disability, and psychiatric features. The KCNT1 gene encodes a sodium-activated potassium channel that regulates excitability in neurons by contributing to the slow hyperpolarization that follows repetitive firing.

Malformations of cortical development (MCDs) have previously been documented in SHE, but only few studies have elucidated their genetic etiologies. Here, we report the co-occurrence, not described previously, of mild MCDs (mMCDs) and KCNT1 pathogenic variants in four subjects with SHE.

Patients and Methods

We performed genetic diagnostic testing in one ADSHE patient (patient A.III.1) previously submitted to epilepsy surgery in whom mMCD was detected by histopathological examination, and in his family relatives (Fig. 1A). A cohort of further 36 published and unpublished patients with KCNT1-related SHE, collected through data sharing with Epilepsy and Genetic Centers in Europe and North America, was reviewed for MRI abnormalities and/or surgical treatment. We collected two additional patients with de novo KCNT1 variants, one with ADSHE (patient B.III.2, Fig. 1B) and one with sporadic SHE (patient C). Both patients underwent epilepsy surgery before genetic testing. A fourth patient (B.III.1) belonging to family B (Fig. 1B) showed MCD at the MRI. Electro-clinical phenotyping was performed by detailed clinical history and video-EEG monitoring including seizure recording. All patients had had 1.5 or 3 Tesla brain MRIs. Epilepsy surgery was performed after long-term scalp and intracranial video-EEG monitoring. Histopathological diagnosis on FFPE neuropathological surgical specimens was made according to the classification of the International League Against Epilepsy (ILAE) Diagnostic Methods Commission. Sequencing was performed on genomic blood DNA using targeted gene panels comprising known epilepsy genes including those known to cause MCD-related epilepsy (i.e., DEPDC5, NPRL2/3, MTOR).

Informed consent from all participants and approval from the local ethics committees were obtained.

Results

Genetic findings

In family A, genetic analysis revealed a c.2849G>A; p.Arg950Gln KCNT1 (NM_020822.2) missense mutation segregating in subjects A.III.1, A.III.2, inherited from their unaffected father, and found in A.II.3 (Fig. 1A), reflecting

**Figure 1.** (A) Pedigree of family A (KCNT1 c.2849G>A; p.Arg950Gln). (B) Pedigree of family B (KCNT1 c.2386T>C; p.Tyr976His). The patient indicated with a dot is an unaffected carrier. Red contours indicate the presence of MCD, dark symbols indicate individuals with focal epilepsy. Individuals with KCNT1 mutations are indicated by m/+ and those negative by +/- FCD, focal cortical dysplasia; PNH, periventricular nodular heterotopia.
the incomplete penetrance seen in KCNT1 families.\textsuperscript{7} Family B (c.2386T>G; p.Tyr796His KCNT1) was previously reported.\textsuperscript{2} Patient C had a de novo c.2800G>A; p.Ala934Thr mutation. All KCNT1 variants were considered as pathogenic given their: a) recurrence in other published SHE cases; b) absence in control databases (gnomAD); c) familial segregation/de novo occurrence (Fig. 1A), and d) in vitro gain-of-function effect of the Tyr796His and Ala934Thr variants on the current magnitude.

**Electro-clinical phenotyping**

*Family A.* Patient A.III.1 is a 23-year-old male with drug-resistant sleep-related frontal lobe seizures since 8 years of age (Table 1). Behavioral disturbances and neuropsychological deficits consistent with frontal lobe dysfunction appeared after epilepsy onset. 3T MRI was unremarkable. Epilepsy surgery was performed at age 14 to attempt to control seizures occurring several times per night, almost every night. After 2 years of postoperative seizure freedom, seizures reappeared with partially modified semiology (Table 1) reaching progressively the same frequency as before surgery (Engel class IV\textsuperscript{8}). Histopathological examination (NeuN immunostaining) showed cortical dyslamination suggesting focal cortical dysplasia (FCD) type Ib (Fig. 2A). In patient A.III.2, seizures were drug-resistant, whereas in patient A.II.3 they were well controlled by carbamazepine. In both patients, 1.5T MRI was normal. Familial history, clinical, and EEG features were consistent with ADSHE.

*Family B.* All four affected members of this family were diagnosed with ADSHE. Patient B.III.2 (previously described\textsuperscript{2}) suffered from drug-resistant sleep-related seizures since the age of 3 years. Brain MRI (1.5T) was unremarkable. At 21 years of age, he underwent epilepsy surgery with resection of the right mesio-lateral frontal region. Histopathological examination (Nissl staining) displayed cortical laminar disorganization indicative of FCD type Ib (not mentioned in the initial publication\textsuperscript{5}) (Fig. 2B). Epilepsy improved and seizure semiology changed after surgery. At 14-years follow up he has only rare diurnal seizures with staring (Engel Class II). Patient B.III.1 is the 37-year-old sister with drug-resistant sleep-related frontal seizures. Brain MRI (1.5T) showed left periventricular nodular heterotopia (PNH) connected by a radial band with the normal-appearing overlying cortex (Fig. 2D). Both patients presented with learning disabilities, severe psychosis, and precocious puberty. Patients B.II.1 and B.I.2 had sleep-related seizures consistent with ADSHE. Brain MRI (1.5T) was normal in patient B.II.1 and not available in patient B.I.2.

**Discussion**

In this study, we report the finding of mMCDs in patients with SHE due to pathogenic variants in KCNT1. Together with the GATOR1-encoding genes,\textsuperscript{9} this study emphasizes the genetic continuum between apparently nonlesional and lesional focal epilepsies.

Our four patients present with electro-clinical features compatible with SHE, and FCD type I or PNH. All patients suffered from severe refractory focal seizures, intellectual disability, and psychiatric disturbances consistent with the phenotype previously reported in KCNT1-related SHE.\textsuperscript{2} In three unrelated patients, epilepsy surgery failed to achieve seizure freedom, although epilepsy severity markedly improved in one (Engel Class II). Neuropathological analysis detected dyslamination compatible with FCD type I, a type of FCD often associated with unsatisfactory seizure control after surgery, with less than 50% of patients achieving seizure freedom,\textsuperscript{10} probably due to the more diffuse nature of FCD type I as compared to FCD type II, which has a better postseizure outcome. The focal onset of seizures documented by intracranial EEG recordings in patients with FCD type I is likely to represent only a portion of a more diffuse epileptogenic network, which probably involves a larger amount of abnormal cortex.\textsuperscript{11} Nevertheless, the transient seizure-free period followed by a change of seizure semiology observed in patients A.III.1 and B.III.2 indicates that the surgical intervention indeed impinged on the epileptogenic network, although the resection probably was not large enough to yield seizure freedom.

A role of KCNT1 in provoking widespread epileptogenesis that sustains seizure propensity after epilepsy surgery is also possible. Structural and molecular alterations (such as ion channel expression/function) in the perilesional region, may also contribute to the epileptogenicity of focal MCDs.\textsuperscript{12} The coexistence of two highly epileptogenic substrates (i.e., MCD and KCNT1 mutation) could underlie the epilepsy severity in these patients. Indeed, KCNT1 mutations and MCDs might reciprocally

influence each other in developing the pathophysiological mechanisms that generate seizures, as suggested in patients with MCD carrying $SCN1A$ mutations.\(^\text{13}\) An alternative hypothesis is the existence of a second-hit somatic mutation that would support the focal cortical lesion, as previously demonstrated in $DEPDC5$-related focal epilepsy,\(^\text{4,14}\) a hypothesis that could not be verified here because of the lack of resected epileptogenic cortex. Given the poor epilepsy surgery outcome, our findings raise the issue whether surgery is an effective treatment in $KCNT1$-related SHE, and, in a broader perspective, whether genetic testing should be included in the presurgical assessment of patients who are considered as possible candidates for epilepsy surgery.\(^\text{15}\)

Interestingly, in the fourth nonoperated patient with ADSHE (patient B.III.1), MRI showed unilateral PNH, a type of MCD that has been shown to be associated with FCD type I in the cortex overlying the nodules.\(^\text{16}\) Negative MRI in three patients (A.III.2, A.II.3 and B.II.1) might depend on the limited sensitivity of current neuroimaging techniques to detect subtle abnormalities, especially FCD type I or, alternatively, it might suggest that $KCNT1$ variants can be associated with lesional and non-lesional epilepsies even within the same family.

The contribution of ion channels in the pathogenesis of MCDs has previously been reported. For instance, dysplastic neurons present in FCDs display strong $K_{\text{v}}4.2$ expression.\(^\text{17}\) Recently, neuropathological investigations in a child diagnosed with a severe $KCNQ2$-related neonatal epileptic encephalopathy, revealed the presence of heterotopic neurons in the deep white matter.\(^\text{18}\) In a knockdown mouse model, $KCNK$ potassium channels dysfunction, resulting in increased frequency of spontaneous calcium influx, impeded physiological neuronal migration in the developing cerebral cortex, possibly playing a role in the genesis of MCD via an activity-dependent mechanism.\(^\text{19}\) Lastly, MCDs in patients with $SCN1A$ and $SCL35A2$ mutations have been documented.\(^\text{13,20}\)

Our study supports an emerging view in which subtle structural brain changes (MRI-undetectable) can occur in epilepsies caused by mutations in ion channel genes and further emphasizes the need for repeated and careful review of high-resolution imaging for subtle
abnormalities, that may not be immediately appreciated, in patients with KCNT1-related focal epilepsies.

Acknowledgments
We thank Roberto Spreafico and Nadia Colombo for their helpful comments and suggestions on the manuscript. We are indebted to the patients and their families for their collaboration in performing this study. This work was supported by the European Research Council (ERC 682345 to SB).
