Marijuana Use by Patients with Multiple Sclerosis

Sheila Gupta; Kelly Fellows, PhD; Bianca Weinstock-Guttman, MD; Jesper Hagemeier, PhD; Robert Zivadinov, MD, PhD; Murali Ramanathan, PhD

Background: With social attitudes about marijuana changing and patients sometimes seeking nonmainstream treatment options, the main goal of this study was to investigate the prevalence of, and factors associated with, marijuana use by patients with multiple sclerosis (MS).

Methods: Adult patients with MS (n = 521) and controls (n = 279) from a study of clinical, neuroimaging, genetic, and environmental factors in MS progression were included. Patients with MS stated whether they had ever used marijuana before MS diagnosis, after MS diagnosis, and in the preceding 3 months as part of an in-person questionnaire. The control group stated whether they had ever used marijuana and in the preceding 3 months.

Results: The percentage of patients with MS reporting ever use of marijuana was 39.9%, compared with 32.7% of controls. Marijuana use in the preceding 3 months was significantly more prevalent among patients with MS (9.4%) compared with controls (0.4%) (P < .001). Marijuana use was most prevalent in male patients with MS (P = .004) and in patients with MS who used complementary and alternative medicine (P = .045). Cigarette smoking was associated with marijuana use in patients with MS (P < .001) and controls (P = .001). Increasing age was associated with decreasing prevalence of marijuana use in the patients with MS (P < 0.001).

Conclusions: Patients with MS are more likely to report recent marijuana use than are people without MS. Owing to potential adverse effects, marijuana use by patients with MS may warrant vigilance by MS caregivers, given shifting social attitudes and the trend towards legalization of marijuana in the United States. Int J MS Care. 2019;21:57-62.

Multiple sclerosis (MS) is a neurologic disease of the central nervous system that causes physical and cognitive disability. Multiple sclerosis is also associated with a diverse range of symptoms, including pain, spasticity, fatigue, balance problems, heat intolerance, bladder problems, and tremors, all of which adversely affect quality of life. Patients with MS often seek nonmainstream treatment options to alleviate their symptoms, such as complementary and alternative medicine (CAM), herbal supplements, and marijuana. Social perceptions and attitudes regarding marijuana use in the United States have shifted in the past decade. Jones et al in 2015 reported that 58% of Americans favored legalization of marijuana, compared with 30% in 2000. The political and legal environment for marijuana use has also changed considerably, particularly in the United States, in part because the legal sale of marijuana is seen as a potential source of tax revenue and in part because of shifting social attitudes among the voting public.

Marijuana use for medical and recreational purposes is now legal in Colorado, Washington, California, Oregon, Alaska, Massachusetts, Maine, and Nevada, all of which have legalized marijuana use via referendum or legislation. Medical marijuana has also been legalized...
The main goal of this study was to investigate the prevalence of marijuana use in patients with MS compared with controls. Another goal was to investigate the associations between marijuana use and clinical factors, such as MS disease course, use of disease-modifying therapies (DMTs), and disability level, and demographic characteristics, such as education level, smoking status, and CAM use.

**Methods**

**Study Population**

**Study Setting**

The data were obtained from an ongoing prospective study of clinical, genetic, and environmental risk factors in MS at the Jacobs Neurological Institute/Baird MS Research Center of the State University of New York at Buffalo. This was a single-center, prospective, observational study. The University at Buffalo Human Subjects Institutional Review Board approved the study protocol. All participants provided written informed consent at enrollment.

**Inclusion and Exclusion Criteria**

For this substudy, only individuals aged 18 years or older were included. People whose responses regarding marijuana use were “don’t know” and those who declined to answer were excluded.

**Clinical Assessments**

The enrolled patients underwent neurologic examinations. Answers to a comprehensive questionnaire were collected in person by an interviewer. The responses to the questionnaire were transcribed by the interviewer. All participants were enrolled and answered the questionnaire prior to the legalization of medical marijuana in New York State in July 2014. The questionnaire included patients’ responses to whether they had used marijuana before MS diagnosis, after MS diagnosis, and in the 3 months preceding the questionnaire. Controls provided responses to whether they had used marijuana in the past and in the preceding 3 months.

**Data Analysis**

Patients with MS were assigned “yes” to marijuana ever use if they answered “yes” to any of the following marijuana use categories: before MS diagnosis, after MS diagnosis, and in the 3 months preceding the questionnaire. Controls provided responses to whether they had used marijuana in the past and in the preceding 3 months.
Data on age (continuous variable), gender (female or transgender female, male or transgender male), education level (college or no college), MS disease course (relapsing remitting, secondary progressive, or primary progressive), DMT treatment status (receiving DMT, not receiving DMT), smoking status (smoked > 100 [tobacco] cigarettes, have not smoked > 100 cigarettes), living status (living alone, or living with a partner and spouse), race (white, African American, Hispanic Latino, Asian, or other), and CAM use (ever used CAM, never used CAM) were obtained from the study database. The following defined CAM: acupuncture, aromatherapy, Ayurveda, Chinese herbal medicine, chiropractic care, electromagnetic therapy, homeopathy, hypnosis, massage, naturopathy, qigong, Reiki, therapeutic touch, bee stings, or other. For all binary variables, the odds ratio (OR) was computed and reported.

The differences between the means of the continuous variable (eg, age between participants who reported marijuana use and those who did not) were assessed using independent samples t tests. The differences in distributions of categorical variables (eg, gender, education level, DMT treatment status) between participants who reported marijuana use and those who did not were assessed using the Fisher exact test for binary variables and the \( \chi^2 \) test for the nonbinary categorical variable.

Associations between marijuana use variables and Expanded Disability Status Scale (EDSS) scores were investigated using ordinal regression, with EDSS score as the dependent variable and age, gender, and marijuana use variable of interest as predictor variables. A multivariate logistic regression was used to investigate the associations between marijuana use as a dependent variable and the following predictor variables: age, gender, ever-smoking cigarettes, MS disease course, and CAM use. Subsequently a stepwise regression analysis (entry \( P = .05 \), removal \( P = .1 \)) was done.

All statistical analyses were conducted using IBM SPSS Statistics for Windows version 24.0 (IBM Corp, Armonk, NY).

### Results

#### Demographic and Clinical Characteristics

This substudy included 521 patients with MS and 279 controls. Table 1 summarizes the demographic characteristics of both groups. Both groups were mostly female (MS: 71.0%, controls: 63.8%) and of white race/ethnicity (MS: 93.1%, controls: 86.6%). The mean ± SD age was 47.6 ± 11.1 years for the MS group compared with 45.9 ± 15.1 years for the control group.

Most of the patients with MS (66.2%) had relapsing-remitting MS. The median (interquartile range) EDSS score for patients with MS was 3.0 (4.0). The mean ± SD disease duration and treatment duration were 15.2 ± 10.5 and 4.32 ± 3.9 years, respectively.

#### Prevalence of Marijuana Use

Ever use of marijuana was not significantly more prevalent in the MS group compared with the control group (39.9% vs 32.7%) (Fisher exact test, \( P = .70 \)). Marijuana use in the past 3 months was significantly higher in the MS group (9.4%) compared with the control group (0.4%) (Fisher exact test, \( P < .001 \)). Fewer patients reported having used marijuana after they were diagnosed with MS (16.1%) compared with before their MS diagnosis (37.2%) (Fisher exact test, \( P < .001 \)).

#### Demographic Factors and Marijuana Use

Ever use of marijuana decreased with increasing age in the MS group (\( P < .001 \)) but not in the control group. Gender was significantly associated with marijuana ever use among patients with MS, with more males reporting marijuana ever use (males 49.7% vs females 35.9%; OR, 1.76; \( P = .004 \)). Gender, however, was not associated with ever use of marijuana in the control group, and education and race were not associated with marijuana ever use in either group. Ever use of marijuana-

### Table 1. Demographic and clinical characteristics of patients with MS and controls

| Characteristic                  | Patients with MS | Controls   |
|--------------------------------|------------------|------------|
| Gender, female: male (% female) | 370:151 (71.0)   | 178:101 (63.8) |
| MS disease course               |                  |            |
| Relapsing remitting             | 345 (66.2)       |            |
| Secondary progressive           | 139 (26.7)       |            |
| Primary progressive             | 37 (7.1)         |            |
| Race/ethnicity                  |                  |            |
| White                           | 483 (93.1)       | 240 (86.6) |
| African American                | 22 (4.2)         | 22 (7.9)   |
| Hispanic Latino                 | 9 (1.7)          | 3 (1.1)    |
| Asian                           | 2 (0.4)          | 9 (3.2)    |
| Other                           | 3 (0.6)          | 2 (.7)     |
| Age, y                          | 47.6 ± 11.1      | 45.9 ± 15.1|
| MS disease duration, y          | 15.2 ± 10.5      |            |
| Treatment duration, y           | 4.32 ± 3.88      |            |
| EDSS score, median [IQR]        | 3.0 [4.0]        |            |

Note: Unless otherwise indicated, values are given as number (percentage) or mean ± SD.

Abbreviations: EDSS: Expanded Disability Status Scale; IQR: interquartile range; MS, multiple sclerosis.

SD age was 47.6 ± 11.1 years for the MS group compared with 45.9 ± 15.1 years for the control group.
na was significantly associated with living status in the MS group only, with patients who lived with a partner or spouse having the highest prevalence of use (5.2%, \( P = .007 \)). Cigarette smoking was associated with marijuana ever use in both patients with MS (53.2% smokers vs 25.4% nonsmokers; OR, 3.33; \( P < .001 \)) and controls (54.6% smokers vs 27.0% nonsmokers; OR, 3.26; \( P < .001 \)). The dependence of the prevalence of ever use of marijuana in the MS and control groups on gender and smoking status is summarized in Figures 1A and 1B, respectively.

**Clinical Factors and Marijuana Use**

The associations between marijuana use and MS disease course, disability level, current DMT status, and CAM use were also investigated. Marijuana use in the past 3 months was associated with disease course (\( P < .001 \)). The percentages of patients with relapsing-remitting, secondary progressive, and primary progressive MS reporting marijuana use in the previous 3 months were 18.3%, 12.3%, and 13.9%, respectively. The use of CAM was associated with marijuana use in patients with MS (\( P = .045 \)) but not in controls. The associations between marijuana ever use and CAM use in both groups are summarized in Figure 1C. No association was found between marijuana ever use in patients with MS and EDSS scores.

**Multivariate Analyses**

To address the contribution of the covariates acting together, multivariate logistic regression analyses were conducted, followed by stepwise regression. Ever use of marijuana was the dependent variable, and age, gender, smoking status, MS disease course, and CAM use were treated as predictor variables. The multivariate logistic regression identified gender (\( P = .004 \)), age (\( P = .0039 \)), cigarette smoking (\( P < .001 \)), and any CAM use (\( P = .006 \)) as significant factors associated with marijuana ever use. A follow-up stepwise regression analysis showed that gender (\( P = .002 \)), age (\( P = .016 \)), smoking status (\( P < .001 \)), and CAM use (\( P = .003 \)) remained significant predictors of marijuana ever use.

**Discussion**

The purpose of the present study was to investigate the factors associated with reported marijuana use in patients with MS and to compare the prevalence of reported marijuana use in patients with MS to that of controls. Our investigation of marijuana use provides useful information regarding the demographic and clinical characteristics of patients with MS and controls who report marijuana use in the United States. Patients with
MS were more likely to report recent marijuana use (within the past 3 months) compared with controls. A greater prevalence of marijuana ever use was observed in younger patients, and in those who reported smoking more than 100 cigarettes in their lifetime in both the MS and control groups. We also found a greater prevalence of marijuana ever use in males versus females in the patients with MS. Marijuana ever use was not associated with race or education level in the MS group. There was a positive association between marijuana ever use and CAM use in the MS group.

The overall prevalence of marijuana ever use among patients with MS in our study was 39.9%, which is comparable to the 43% reported in previous studies of patients with MS in the United Kingdom and Canada. The National Institute of Drug Abuse estimates that 35.9% of 12th graders in the United States and 12.2% of US citizens aged 26 years or older report marijuana use in the past year.

The outcomes of future clinical trials of pharmaceutical-grade, cannabis-based medicine for the treatment of symptoms related to MS may have the potential to influence patients’ perceptions of smoked marijuana, particularly in states where marijuana is legal. Patients eager to adopt marijuana as part of their treatment regimen may overlook the risks associated with the lack of control over the dose ingested, exposure to marijuana cigarette smoke, and lack of standardization of dose form with smoked marijuana, none of which have been extensively investigated in a clinical setting. Interestingly, in a placebo-crossover study of 37 participants by Corey-Bloom et al, spasticity decreased by 2.74 points on the Ashworth scale and pain reduced by an average of 5.28 points on the visual analogue scale after patients had smoked cannabis for 3 days. However, a significant decrease in cognition was reported among patients just after they had smoked marijuana, as measured with the Paced Auditory Serial Addition Test. These findings suggest that smoked marijuana may alleviate some of the symptoms associated with MS, but that its apparent effect on cognition remains a concern. In addition, as marijuana use becomes more mainstream, reports of adverse events associated with it could modify public and patient perceptions.

Recently, Cofield et al examined survey responses from 5481 participants in the North American Research Committee on Multiple Sclerosis (NARCOMS) Registry, which assessed interest in and use of marijuana before and after MS diagnosis. The researchers found that 64% of the participants reported marijuana use prior to diagnosis, and 47% would consider marijuana as a possible supplement to treat MS symptoms. Additionally, 91% of respondents believed that marijuana use should be legalized in some form. The results from this study highlight the interest in legalization of marijuana use among patients with MS.

The present study was cross-sectional and has all the limitations of such a design, including the risks of recall bias. During this study, marijuana was illicit for medicinal purposes in New York State. Thus, it is possible that marijuana use was underreported among the study participants. Despite this limitation, the present study provides a useful profile of the factors associated with marijuana use in patients with MS. A questionnaire study of patients with MS (n = 220) conducted in Nova Scotia by Clark et al found that men were significantly more likely to use medical cannabis than women, which corroborates our findings in this study population. However, Chong et al found no differences in prevalence of marijuana use between male and female patients with MS in the United Kingdom.

In the present study, we found no evidence for associations between marijuana use in patients with MS and educational level or race. These results are concordant with the findings from Chong et al, who investigated marijuana use in 254 patients with MS in the United Kingdom. Our findings, which indicate a negative association between age and marijuana use for treatment in MS, were not observed in the studies conducted in the United Kingdom or Canada. However, the age

**PRACTICE POINTS**

- The prevalence of patients with MS reporting ever use of marijuana was similar to that of controls. In both the MS and control groups marijuana use was significantly associated with cigarette smoking.
- Patients with MS reported recent use of marijuana (within preceding 3 months) more than controls.
- Greater prevalence of marijuana use was associated with male gender, younger age, relapsing-remitting MS disease course, cigarette smoking, use of complementary alternative medicine, and living with a spouse or partner.
dependence in our MS sample is consistent with the age-dependent pattern of marijuana use in the US population at large.5

Interestingly, use of CAM was also associated with marijuana ever use in patients with MS. To our knowledge, our study is the first to investigate the associations of marijuana use with CAM use in patients with MS. Our findings suggest that patients with MS who use CAM may be more likely to use marijuana as an alternative to standardized DMT for treatment of MS-related symptoms.

In conclusion, we have identified several potential demographic and clinical characteristics associated with self-treatment with marijuana in patients with MS. With the increasing interest in use of marijuana to treat the debilitating symptoms associated with chronic diseases such as MS, there is a need for well-controlled clinical studies to evaluate the safety, feasibility, and effectiveness of such treatment.
