Editor: ..... 

Abstract

The use of quadratic discriminant analysis (QDA) or its regularized version (R-QDA) for classification is often not recommended, due to its well-acknowledged high sensitivity to the estimation noise of the covariance matrix. This becomes all the more the case in unbalanced data settings for which it has been found that R-QDA becomes equivalent to the classifier that assigns all observations to the same class. In this paper, we propose an improved R-QDA that is based on the use of two regularization parameters and a modified bias, properly chosen to avoid inappropriate behaviors of R-QDA in unbalanced settings and to ensure the best possible classification performance. The design of the proposed classifier builds on a refined asymptotic analysis of its performance when the number of samples and that of features grow large simultaneously, which allows to cope efficiently with the high-dimensionality frequently met within the big data paradigm. The performance of the proposed classifier is assessed on both real and synthetic data sets and was shown to be much better than what one would expect from a traditional R-QDA.

1. Introduction

Discriminant analysis encompasses a wide variety of techniques used for classification purposes. These techniques, commonly recognized among the class of model-based methods in the field of machine learning (Devijver and Kittler, 1982), rely merely on the fact that we assume a parametric model in which the outcome is described by a set of explanatory variables that follow a certain distribution. Among them, we particularly distinguish linear discriminant analysis (LDA) and quadratic discriminant analysis (QDA) as the most representatives. LDA is often connected or confused with Fisher discriminant analysis (FDA) (Fisher, 1936), a method of projecting the data into a subspace and turns out to coincide with LDA when the target subspace has two dimensions. Both LDA and QDA are obtained by maximizing the posterior probability under the assumption that observations follow normal distribution, with the single difference that LDA assumes common covariances across classes while QDA assumes the most general situation with classes possessing different means and covariances. If the data follow perfectly the normal distributions and the statistics are perfectly known, QDA turns out to be the optimal classifier that achieves the lowest possible classification error rate (J. Friedman and Tibshirani, 2009). It coincides with LDA when the covariances are equal but outperforms it when they are different. However, in practical scenarios, the use of QDA was not always shown to yield the expected performances. This is because the mean and covariance of each class, which are in general unknown, are estimated based on available training data with perfectly known classes. The obtained estimates are then used as plug-in estimators in the classification rules associated with LDA and QDA. The estimation error of the class statistics causes a provably degradation of the performances which reaches very high levels when the number of samples is comparable or less than their dimensions. In this latter situation, QDA and LDA, relying on computing the inverse of the covariance matrix could not be used. To overcome this issue, one technique consists in using a regularized estimate of the covariance matrix as a plug-in estimator of the covariance matrix giving the name to Regularized LDA (R-LDA) or Regularized QDA (R-QDA) to the associated classifiers. However, this solution does not allow for a significant reduction of the estimation noise. The situation is even worse for R-QDA, since the number of samples used to estimate the covariance matrix of each class is lower than that of LDA. This is probably the reason why LDA provided in many scenarios better performances than QDA, although it might wrongly consider the covariances across classes equal.

A question of major theoretical and practical interest is to investigate to which extent the estimation noise of the covariance matrix impacts the performances of R-LDA and R-QDA. In this respect, the study of LDA and subsequently that of R-LDA have received a particular attention, dating back to the early works of Raudys (Raudys, 1967), before being investigated again using recent advances of random matrix theory tools in a recent series of works (Zollanvari and Dougherty, 2015; Wang and Jiang, 2018). However, the theoretical analysis of QDA and R-QDA is more scarce and very often limited to specific situations in which the number of samples is higher than that of the dimensions of the statistics (McFarland and Richards, 2002), or under specific structures of the covariance matrices (Cheng, 2004; Li and Shao, 2015; Jiang et al., 2015). It was only recently that the work in (Elkhalil et al., 2017) considered the analysis of R-QDA for general structures of the covariance matrices and identified the necessary asymptotic conditions under which...
QDA does not exhibit the trivial behavior by which it returns always the same class or randomly guess it. Particularly, the work in (Elkhalil et al., 2017) assumes balanced data across classes, because otherwise R-QDA would tend to assign all observations to one class, thereby limiting the use of R-QDA in general settings.

This lies behind the main motivation of the present work. Based on a careful investigation of the asymptotic behavior of R-QDA under unbalanced settings in binary classification problems, we propose to amend the traditional R-QDA to cope with cases in which the proportions of training data from both classes are not equal. The new classifier is based on using two different regularization parameters instead of a common regularization parameter as well as an optimized bias properly chosen to minimize the misclassification error rates. Interestingly, we show that the proposed classifier not only outperforms R-LDA and R-QDA but also other state-of-the-art classification methods, opening promising avenues for the use of the proposed classifier in practical scenarios.

The rest of the paper is organized as follows: In section 2, we provide an overview of the quadratic discriminant classifier and identify the issues related to the use of this classifier in unbalanced settings. In section 3, we propose an improved version of the R-QDA classifier that overcomes all these problems and we design a consistent estimator of the misclassification error rate that can be used as an alternative to the traditional cross-validation approach. Finally, Section 4 contains simulations on both synthetic and real data that confirm our theoretical results.

Notations Scalars, vectors and matrices are respectively denoted by non-boldface, boldface lowercase and boldface uppercase characters. $\mathbf{0}_{p \times n}$ and $\mathbf{1}_{p \times n}$ are respectively the matrix of zeros and ones of size $p \times n$, $\mathbf{I}_p$ denotes the $p \times p$ identity matrix. The notation $\| \cdot \|$ stands for the Euclidean norm for vectors and the spectral norm for matrices. $(\cdot)^T$, $\text{Tr}[\cdot]$ and $|\cdot|$ stands for the transpose, the trace and the determinant of a matrix respectively. For two functions $f$ and $g$, we say that $f = O(g)$, if $\exists 0 < M < \infty$ such that $|f| \leq Mg$. We say also that $f = \Theta(g)$, if $\exists 0 < C_1 < C_2 < \infty$ such that $C_1g \leq |f| \leq C_2g$. $\mathcal{P}(\cdot), \overset{p}{\rightarrow} 0$ and $\overset{a.s.}{\rightarrow}$ respectively denote the probability measure, the convergence in probability and the almost sure convergence of random variables. $\Phi(\cdot)$ denotes the cumulative density function (CDF) of the standard normal distribution, i.e. $\Phi(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}} dt$.

2. Regularized quadratic discriminant analysis

As aforementioned, R-QDA is equivalent to the classifier that assigns all observations to the same class when designed out of a set of unbalanced training data samples. Such a behavior has led the authors in (Elkhalil et al. 2017) to consider the analysis of R-QDA only under a balanced training sample. In this section, we show that this behavior can be easily predicted through a close examination of the mean and variance of the classification rule associated with R-QDA. This constitutes an important step that will pave the way towards the improved R-QDA presented in the next section. But prior to that, we shall first review the traditional R-QDA for binary classification.
2.1 Regularized QDA for binary classification

For ease of presentation, we focus on binary classification problems where we have two distinct classes. We assume that the data follow a Gaussian mixture model, such that observations in class $C_i$, $i \in \{0, 1\}$ are drawn from a multivariate Gaussian distribution with mean $\mu_i$ and covariance $\Sigma_i$. More formally, we assume that

$$x \in C_i \iff x = \mu_i + \Sigma_i^{1/2}z, \quad \text{with} \quad z \sim \mathcal{N}(0, I_p) \quad (1)$$

Let $\pi_i$, $i = 0, 1$ denote the prior probability that $x$ belongs to class $C_i$. The classification rule associated with the QDA classifier is given by

$$W^{QDA}(x) = -\frac{1}{2} \log |\Sigma_0| - \frac{1}{2} x^T (\Sigma_0^{-1} - \Sigma_1^{-1}) x + x^T \Sigma_0^{-1} \mu_0$$

$$- x^T \Sigma_1^{-1} \mu_1 - \frac{1}{2} \mu_0^T \Sigma_0^{-1} \mu_0 + \frac{1}{2} \mu_1^T \Sigma_1^{-1} \mu_1 - \log \frac{\pi_1}{\pi_0} \quad (2)$$

which is used to classify the observations based on the following rule:

$$\begin{aligned}
&\begin{cases}
  x \in C_0 & \text{if} & W^{QDA} > 0 \\
  x \in C_1 & \text{otherwise}
\end{cases} \quad (3)
\end{aligned}$$

As seen from (2), the classification rule of QDA involves the true parameters of the Gaussian distribution, namely the means and covariances associated with each class. In practice, these parameters are not known. One approach to solve this issue is to estimate them using the available training data. The obtained estimates are then used as plug-in estimators in (2). In particular, consider the case in which $n_i, i \in \{0, 1\}$ training observations for each class $C_i, i \in \{0, 1\}$ are available and denote by $T_0 = \{x_l \in C_0\}_{l=1}^{n_0}$ and $T_1 = \{x_l \in C_1\}_{l=n_0+1}^{n_0+n_1}$ their respective samples. The sample estimates of the mean and covariances of each class are then given by:

$$\tilde{\mu}_i = \frac{1}{n_i} \sum_{l \in T_i} x_l, \quad i \in \{0, 1\}$$

$$\tilde{\Sigma}_i = \frac{1}{n_i-1} \sum_{l \in T_i} (x_l - \tilde{\mu}_i) (x_l - \tilde{\mu}_i)^T, \quad i \in \{0, 1\}$$

In case the number of samples $n_0$ or $n_1$ is less than the number of features, the use of the sample covariance matrix as plug-in estimator is not permitted since the inverse could not be defined. A popular approach to circumvent this issue is to consider a regularized estimator of the inverse of the covariance matrix given by

$$H_i(\gamma) = \left( I_p + \gamma \tilde{\Sigma}_i \right)^{-1}, i \in \{0, 1\} \quad (4)$$

where $\gamma$ is a regularization parameter, which serves to shrink the sample covariance matrix towards identity. Replacing $\Sigma_i^{-1}$ by $H_i(\gamma)$ yields the following classification rule

$$\tilde{W}^{R-QDA}(x) = -\frac{1}{2} \log \left| \frac{H_0(\gamma)}{H_1(\gamma)} \right| - \frac{1}{2} (x - \tilde{\mu}_0)^T H_0(\gamma) (x - \tilde{\mu}_0)$$

$$+ \frac{1}{2} (x - \tilde{\mu}_1)^T H_1(\gamma) (x - \tilde{\mu}_1) - \log \frac{\pi_1}{\pi_0} \quad (5)$$
The classifier R-QDA assigns wrongly observation \( \mathbf{x} \) if \( \hat{W}^{R-QDA}(\mathbf{x}) < 0 \) when \( \mathbf{x} \in \mathcal{C}_0 \) or if \( \hat{W}^{R-QDA}(\mathbf{x}) > 0 \) when \( \mathbf{x} \in \mathcal{C}_1 \). Conditioning on the training sample \( \mathcal{T}_i, i \in \{0, 1\} \), the classification error associated with class \( \mathcal{C}_i \), is thus given by

\[
\epsilon_i^{R-QDA} = \mathbb{P} \left[ (-1)^i \hat{W}^{R-QDA}(\mathbf{x}) < 0 \mid \mathbf{x} \in \mathcal{C}_i, \mathcal{T}_0, \mathcal{T}_1 \right] \tag{6}
\]

which gives the following expression for the total misclassification error probability

\[
\epsilon^{R-QDA} = \pi_0 \epsilon_0^{R-QDA} + \pi_1 \epsilon_1^{R-QDA} \tag{7}
\]

### 2.2 Identification of the problems of the R-QDA classifier in unbalanced data settings

In this section, we unveil several issues pertaining to the use of the classification rule (2) of R-QDA in high dimensional settings. These issues can be revealed through a careful investigation of the asymptotic distribution of the classification rule associated with R-QDA. We first recall that the classification rule associated with R-QDA is a quadratic function of the Gaussian test observation \( \mathbf{x} \) and as such behaves like a Gaussian distribution with a certain mean and variance as long as the Lyapunov conditions are met (Billingsley, 1995). To get direct insights into how the R-QDA behaves, we assume that there is asymptotically no error in assuming that \( \frac{1}{\sqrt{p}} \hat{W}^{R-QDA}(\mathbf{x}) \) when \( \mathbf{x} \) belongs to class \( \mathcal{C}_i \) behaves like a Gaussian distribution with mean \( \mathbb{E}_i = E_x \left( \frac{1}{\sqrt{p}} \hat{W}^{R-QDA}(\mathbf{x}) \right) \) and variance \( \nabla_i = \text{var} \left( \frac{1}{\sqrt{p}} \hat{W}^{R-QDA}(\mathbf{x}) \right) \) where here the expected value and variances are taken with respect to the distribution of the testing observation \( \mathbf{x} \), and the scaling factor \( \frac{1}{\sqrt{p}} \) is used to produce fluctuations of order \( O(1) \). For the R-QDA to lead to appropriate behavior (including perfect classification error rate), the means \( \mathbb{E}_i \) should be of opposite signs (namely \( \mathbb{E}_0 > 0 \) and \( \mathbb{E}_1 < 0 \)) and at least of order \( O(1) \) while the variances \( \nabla_i \) be \( O(1) \). This latter condition on the variance is already ensured provided that spectral norms of the covariances is bounded and the difference between mean vectors have a norm at most \( O(p^{\frac{1}{2}}) \). Under these assumptions, and taking the expectation over the testing observation, \( \mathbb{E}_i \) and \( \nabla_i \) satisfy:

\[
\mathbb{E}_i = \frac{1}{2\sqrt{p}} \log \left| \frac{\mathbf{H}_0(\gamma)}{\mathbf{H}_1(\gamma)} \right| - \frac{1}{2\sqrt{p}} \left( \mu_i - \mu_0 \right)^T \mathbf{H}_0(\gamma) \left( \mu_i - \mu_0 \right) - \frac{1}{\sqrt{p}} \log \frac{\pi_1}{\pi_0} + \frac{1}{2\sqrt{p}} \left( \mu_i - \mu_1 \right)^T \mathbf{H}_1(\gamma) \left( \mu_i - \mu_1 \right) - \frac{1}{2\sqrt{p}} \text{Tr} \left[ \Sigma_i \mathbf{H}_0(\gamma) \right] + \frac{1}{2\sqrt{p}} \text{Tr} \left[ \Sigma_i \mathbf{H}_1(\gamma) \right] \tag{8}
\]

\[
\nabla_i = O(1) \tag{9}
\]

It can be easily seen that under the assumption that \( \| \mu_1 - \mu_0 \| = O(p^{\frac{1}{2}}) \), and the spectral norms of \( \Sigma_i, i \in \{0, 1\} \) are bounded uniformly in \( p \), the means \( \mathbb{E}_i \) are asymptotically approximated as:

\[
\mathbb{E}_i = \frac{1}{2\sqrt{p}} \log \left| \frac{\mathbf{H}_0(\gamma)}{\mathbf{H}_1(\gamma)} \right| - \frac{1}{2\sqrt{p}} \text{Tr} \left[ \Sigma_i \mathbf{H}_0(\gamma) \right] + \frac{1}{2\sqrt{p}} \text{Tr} \left[ \Sigma_i \mathbf{H}_1(\gamma) \right] + O(1) \tag{10}
\]

Several important remarks are in order regarding (10). First, we note that the prior probabilities \( \pi_1 \) and \( \pi_0 \) do not play asymptotically any role in the classification, since the
term \( \frac{1}{\sqrt{np}} \log \frac{s_1}{s_0} \) tends to zero. Second, one can easily see that if the distance between the covariances is such that \( \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_1 H_0] - \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_0 H_0] = O(1) \) and \( \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_0 H_1] - \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_1 H_1] = O(1) \) which occurs for instance when \( \Sigma_1 - \Sigma_0 \) has at most rank \( \sqrt{p} \) (Elkhalil et al., 2017), the means \( \overline{s}_i \) are given by:

\[
\overline{s}_i = \frac{1}{2\sqrt{p}} \log \left| \frac{H_0(\gamma)}{H_1(\gamma)} \right| - \frac{1}{2\sqrt{p}} \text{Tr}[\Sigma_1 H_0(\gamma)] + \frac{1}{2\sqrt{p}} \text{Tr}[\Sigma_1 H_1(\gamma)] + O(1). 
\]

It appears thus that the direct use of R-QDA poses two main issues. The first one concerns the bias term, the contribution of which in \( \overline{s}_1 \) and \( \overline{s}_0 \) is asymptotically independent of the mean vectors and the prior probabilities. This makes R-QDA perform classification only on the basis of the covariance matrix. It is thus important to modify the bias term. The second issue is that unlike the balanced case for which \( \overline{s}_1 \) and \( \overline{s}_0 \) were shown \( O(1) \) when there are exactly \( \Theta(\sqrt{p}) \) of eigenvalues with order \( \Theta(1) \) (Elkhalil et al., 2017), \( \overline{s}_1 \) and \( \overline{s}_0 \) are up to order \( O(\sqrt{p}) \) the same for both classes. This can be clearly illustrated through Figure 1 which displays the histogram associated with the classification rule of R-QDA and that of QDA with perfect knowledge of the statistics. As can be seen, the use of R-QDA does not allow discrimination between both classes since the means of the classification rule under class \( C_0 \) or class \( C_1 \) at the highest order is the same. Based on random matrix theory results, we can prove that such a behavior is caused by the use of the same regularization parameter for both \( H_0 \) and \( H_1 \). In light of these observations, we propose to replace the classification rule of R-QDA by the following rule:

\[
\hat{W}^{R-QDA_{imp}}(x) = -\theta \frac{1}{2\sqrt{p}} - \frac{1}{2} (x - \hat{\mu}_0)^T H_0(\gamma_0) (x - \hat{\mu}_0) + \frac{1}{2} (x - \hat{\mu}_1)^T H_1(\gamma_1) (x - \hat{\mu}_1) 
\]

\[(11)\]
where 1) $\gamma_0$ and $\gamma_1$ are two regularization parameters for each class carefully devised so that the means $\mathbb{E}_x \left[ \hat{W}^{R-QDA_{imp}}(x) \right]$ when $x \in C_0$ or $C_1$ are $O(1)$ and reflects the class under consideration and 2) $\theta$ is a bias term that will be set to the value that minimizes the asymptotic classification error rate.

3. Design of the improved R-QDA classifier

In this section, we propose an improved design of the R-QDA classifier that fixes the aforementioned issues met in unbalanced settings. The design will be based on asymptotic analysis of the statistics in (11) under the following asymptotic regime, which was also considered in (Elkhalil et al., 2017):

**Assumption. 1** (Data scaling). $\frac{p}{n} \to c \in (0, \infty)$ and $\frac{n_0}{n_1} \to c \in (0, 1)$

**Assumption. 2** (Mean scaling). $\|\mu_0 - \mu_1\|^2 = \Theta(\sqrt{p})$

**Assumption. 3** (Covariance scaling). $\|\Sigma_i\| = \Theta(1), i = 0, 1$

**Assumption. 4.** Matrix $\Sigma_0 - \Sigma_1$ has exactly $\Theta(\sqrt{p})$ eigenvalues of order $\Theta(1)$. The remaining eigenvalues are of order $\Theta\left(\frac{1}{\sqrt{p}}\right)$.

Assumption 1 and 3 are standard and are often used to describe a growth regime in which the number of features scales comparably with that of samples and the spectral norm of both covariance matrices remain bounded. Assumption 2 defines the smallest distance between the mean vectors so that they are used to discriminate between both classes, while Assumption 4, introduced in (Elkhalil et al., 2017) is used to ensure that the difference between covariances has a contribution that is of the same order of magnitude as that of the difference between the mean vectors.

Under the asymptotic regime specified by Assumptions 1-4 and along the same lines as in (Elkhalil et al., 2017), we analyze the classification error rate of the proposed classifier with classification rule 11. Before presenting the corresponding result, we shall first introduce the following notations which defines deterministic objects that naturally appears when using random matrix theory results.

For $i = 0, 1$, let $\delta_i$ be the unique positive solution to the following equation:

$$\delta_i = \frac{1}{n_i} \text{Tr} \left[ \Sigma_i \left( I_p + \frac{\gamma_i}{1 + \gamma_i \delta_i} \Sigma_i \right)^{-1} \right]$$

The existence and uniqueness of $\delta_i$ follows from standard results in random matrix theory (Hachem et al., 2008). For $i = 0, 1$, we also define matrices $T_i$, as:

$$T_i = \left( I_p + \frac{\gamma_i}{1 + \gamma_i \delta_i} \Sigma_i \right)^{-1}$$

and the scalars $\phi_i$ and $\tilde{\phi}_i$ as:

$$\phi_i = \frac{1}{n_i} \text{Tr} \left[ \Sigma_i^2 T_i^2 \right], \quad \tilde{\phi}_i = \frac{1}{(1 + \gamma_i \delta_i)^2}$$

With these notations at hand, we are now in position to state the first asymptotic result:

**Theorem 1** Under Assumption 1-4, and assuming that the regularization parameters $\gamma_0$
and $\gamma_1$ are $\Theta(1)$, the classification error rate associated with class $C_i$ satisfies:

$$
\epsilon_{i-QDA}^R - \Phi \left( \frac{-1}{\sqrt{\frac{1}{B_i} + 4r_i}} \right) \xrightarrow{p} 0
$$

where

$$
\xi_i \triangleq \frac{1}{\sqrt{p}} \left[ (-1)^i \mu^T T_{1-i} \mu \right] + \theta \quad \text{with} \quad \mu = \mu_1 - \mu_0
$$

$$
b_i = \frac{1}{\sqrt{p}} \text{Tr} \Sigma_i (T_1 - T_0)
$$

$$
B_i = \frac{1}{\sqrt{p}} \text{Tr} \Sigma_i (T_1 - T_0)
$$

$$
r_i = \frac{1}{p} \mu^T \Sigma_0 (T_1 \Sigma_i T_0)
$$

**Proof.** The proof follows along the same lines in (Elkhalil et al., 2017) and is as such omitted.

**Remark:** Under Assumption 4, it can be shown that $B_i$ can asymptotically be simplified to

$$
B_i \triangleq 2n_i \gamma_i^2 \phi_i \phi_i^2 + O(\frac{1}{\sqrt{p}})
$$

Moreover, the term $r_i$ is $O(\frac{1}{\sqrt{p}})$ and as such converges to zero as $p, n$ grow to infinity. However, in our simulations, we chose to work with the non-simplified expressions for $B_i$ and to keep the term $r_i$, since we observed that in doing so a better accuracy is obtained in finite-dimensional simulations.

The result of Theorem 1 allows to provide guidelines on how to choose $\gamma_0$ and $\gamma_1$ and the optimal bias $\theta$. As discussed before, the design should require the mean of the classification rule to be $\Theta(1)$ and to reflect the class under consideration. This mean is represented in the asymptotic expression of the classification error rate by the quantity $\xi_i - b_i$ which, at first sight, is $\Theta(\sqrt{p})$ as $b_i = \Theta(\sqrt{p})$ and $\xi_i = \Theta(1)$. Moreover, the class of the testing observation is not reflected in $b_i$ since under Assumption 3-4, in case $b_i = O(\sqrt{p})$, $b_i = \frac{1}{\sqrt{p}} \text{Tr} \Sigma_1 (T_1 - T_0) + \Theta(1)$. To solve this issue, we need to design $\gamma_1$ and $\gamma_0$ such that $b_i$ is $\Theta(1)$ or equivalently,

$$
\frac{1}{p} \text{Tr} \Sigma_1 (T_1 - T_0) = \Theta(\frac{1}{\sqrt{p}})
$$

so that $\gamma_0$ becomes different from $\gamma_1$ at its highest order. To this end, we prove that it suffices to select the regularization parameter associated with the class with the largest number of samples as:

**Theorem 2** Under assumption 1-4, and assume that $n_1 > n_0$, if

$$
\gamma_1 = \frac{\gamma_0}{1 - \left( \frac{1}{n_1} - \frac{1}{n_0} \right) \gamma_0 \text{Tr} \Sigma_0 T_0^T},
$$

8
where $\gamma_0$ is fixed to a given constant then $\bar{b}_i = O(1)$.

**Proof.** See Appendix A.

It is worth mentioning that in the balanced case, plugging $n_0 = n_1$ into (21) yields $\gamma_1 = \gamma_0$. It is thus not necessary to use different regularization parameters when the classes are balanced. With this choice of the regularization parameters being set, the optimal bias can be chosen so that the asymptotic classification error rate given by:

$$
\tau = \pi_0 \Phi \left( -\xi_0 - \bar{b}_0 \sqrt{2B_0} \right) + \pi_1 \Phi \left( -\xi_1 - \bar{b}_1 \sqrt{2B_1} \right)
$$

is minimized.

**Theorem 3** The optimal bias that allows to minimize the asymptotic classification error rate is given by:

$$
\theta^* = \frac{\beta_1 - \beta_0}{2} - \frac{2\alpha^2}{\beta_1 + \beta_0} \log \left( \frac{\pi_1}{\pi_0} \right) \quad (22)
$$

where

$$
\begin{align*}
\beta_0 &= \frac{1}{\sqrt{p}} \left[ -\mu^T T_1 \mu \right] - \frac{1}{\sqrt{p}} \text{Tr} \left[ \Sigma_0 (T_1 - T_0) \right] \\
\beta_1 &= \frac{1}{\sqrt{p}} \left[ -\mu^T T_0 \mu \right] + \frac{1}{\sqrt{p}} \text{Tr} \left[ \Sigma_1 (T_1 - T_0) \right] \\
\alpha &= \sqrt{2B_0}
\end{align*}
$$

**Proof.** See Appendix B.

Before proceeding further, it is important to note that thanks to the careful choice of the regularization parameters $\gamma_0$ and $\gamma_1$ provided in Theorem 2, the term $\frac{1}{\sqrt{p}} \text{Tr} \left[ \Sigma_i (T_1 - T_0) \right]$ is $\Theta(1)$ for $i \in \{0, 1\}$, Additionally, it can be shown easily that the term $\frac{1}{\sqrt{p}} \left[ -\mu^T T_i \mu \right]$ is of order $\Theta(1)$. As a result, both $\beta_0$ and $\beta_1$ are $\Theta(1)$.

On another note, it is worth mentioning that even in the case of balanced classes $n_0 = n_1$, characterized by $\gamma_1 = \gamma_0$ as proved in Theorem 2, the optimal bias is different from the one used in R-QDA. As such, the proposed design improves on the traditional R-QDA studied in (Elkhalil et al., 2017) in the balanced case by optimally adapting the bias term to the case where the covariance matrix are not known.

Theorem 2 and Theorem 3 can be used to obtain an optimized design of the proposed R-QDA classifier. As can be seen, the improved classifier employs only one regularization parameter associated with the class that presents the smallest number of training samples. Assume $C_0$ is such a class. The regularization parameter associated with the other class cannot be arbitrarily chosen and should be set as (21), while the bias is selected according to (22). However, pursuing this design is not possible in practice due to the dependence of (21) and (22) on the true covariance matrices. To solve this issue, we propose in the following theorem a consistent estimator to estimate quantities arising in (21) and (22) that depend only on the training samples.

**Theorem 4** Assume $n_1 > n_0$ and let $\gamma_0$ be the regularization parameter associated with class $C_0$. Let $\hat{\delta}_0$ be given by:

$$
\hat{\delta}_0 = \frac{1}{\gamma_0} \frac{p}{n_0} - \frac{1}{n_0} \text{Tr} \left[ H_0(\gamma_0) \right]
$$

$$
\frac{1}{\gamma_0} 1 - \frac{p}{n_0} + \frac{1}{n_0} \text{Tr} \left[ H_0(\gamma_0) \right]
$$
and define $\hat{\gamma}_1$ as:

$$\hat{\gamma}_1 = \frac{\gamma_0}{1 - \gamma_0 \left(\frac{n_0 \delta_0}{n_1} - \delta_0\right)}$$

(23)

Then,

$$\hat{\gamma}_1 \xrightarrow{a.s.} 0$$

where $\gamma_1$ is given in (21). Define $\hat{\beta}_0$, $\hat{\beta}_1$ and $\hat{\alpha}$ as:

$$\hat{\beta}_0 = -\frac{1}{\sqrt{p}} (\hat{\mu}_0 - \hat{\mu}_1)^T H_1(\hat{\gamma}_1) (\hat{\mu}_0 - \hat{\mu}_1) - \frac{1}{\sqrt{p}} \text{Tr} \left[ \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \right] + \frac{n_0}{p} \delta_0$$

$$\hat{\beta}_1 = -\frac{1}{\sqrt{p}} (\hat{\mu}_0 - \hat{\mu}_1)^T H_0(\hat{\gamma}_0) (\hat{\mu}_0 - \hat{\mu}_1) - \frac{1}{\sqrt{p}} \text{Tr} \left[ \hat{\Sigma}_1 H_0(\hat{\gamma}_0) \right] + \frac{n_1}{p} \delta_1$$

(24)

$$\hat{\alpha} = \sqrt{2 \hat{B}_0}$$

where $\hat{B}_0$ writes as:

$$\hat{B}_0 = \left(1 + \gamma_0 \delta_0 \right)^4 \frac{1}{p} \text{Tr} \left[ \hat{\Sigma}_0 H_0(\hat{\gamma}_0) \hat{\Sigma}_0 H_0(\hat{\gamma}_0) \right] - \frac{n_0}{p} \gamma_0^2 \left(1 + \gamma_0 \delta_0 \right)^2 - \frac{1}{p} \text{Tr} \left[ \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \right]$$

$$- \frac{n_0}{p} \left( \frac{1}{n_0} \text{Tr} \left[ \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \right] \right)^2 - 2 \left(1 + \gamma_0 \delta_0 \right)^2 \frac{1}{p} \text{Tr} \left[ \hat{\Sigma}_0 H_0(\hat{\gamma}_0) \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \right]$$

$$+ \delta_0 \left(1 + \gamma_0 \delta_0 \right) \frac{2}{p} \text{Tr} \left[ \hat{\Sigma}_0 H_1(\hat{\gamma}_1) \right]$$

(25)

Let $\hat{\theta}^*$ be given by:

$$\hat{\theta}^* = \frac{\hat{\beta}_1 - \hat{\beta}_0}{2\hat{\beta}_1 + \hat{\beta}_0} - \frac{2\hat{\alpha}^2}{\hat{\beta}_1 + \hat{\beta}_0} \log\left(\frac{\pi_1}{\pi_0}\right)$$

(26)

Then,

$$\hat{\theta}^* - \theta^* \xrightarrow{a.s.} 0$$

where $\theta^*$ is given in (22).

Proof. See Appendix C.

It is worth mentioning that unlike $\gamma_0$, $\gamma_1$ is random. It does not satisfy with equality (21) but ensures (20) with high probability. Its use as a replacement of $\gamma_1$ would lead asymptotically to the same results as the improved classifier using $\gamma_1$.

With these consistent estimators at hand, we are now in position to present the improved design of the R-QDA classifier:

---

**Algorithm 1:** Improved design of the R-QDA classifier.

**Input:** Assuming $n_1 \geq n_0$, let $\gamma_0$ the regularization parameter associated with class $C_0$, $T_0 = \{x_i\}_{i=1}^{n_0}$ training samples in $C_0$ and $T_1 = \{x_i\}_{i=n_0+1}^{n_0+n_1}$

**Output:** Estimation of the parameters $\gamma_1$ and $\theta^*$ to be plugged in (11)

1. Compute $\hat{\gamma}_1$ as in (23)
2. Compute $\hat{\theta}$ as in (26)
3. Return $\hat{\theta}$ and $\hat{\gamma}_1$ that will be plugged in the classification rule (11).

The improved design described in Algorithm 1 depends on the regularization parameter $\gamma_0$ associated with the class with the smallest number of training samples. One possible way to adjust this parameter is to resort to a traditional cross-validation approach which consists in estimating using a set of testing data the classification error rate for a set of candidate values for the regularization parameter $\gamma_0$. Such an approach is however computationally expensive and could not be used to test a large number of candidate values for $\gamma_0$. As an alternative we propose rather to build a consistent estimator of the classification error rate based on results from random matrix theory. This is the objective of the following theorem:

**Theorem 5** Under Assumptions 1-4, a consistent estimator of the misclassification error rate associated with class $C_i$ is given by:

$$\hat{\epsilon}_i = \Phi \left( (-1)^i \frac{\hat{\xi}_i - \hat{b}_i}{\sqrt{2\hat{B}_i + 4\hat{r}_i}} \right)$$

where $\hat{B}_0$ is given in (25) and

$$\hat{\xi}_i = \hat{\delta}^* - \frac{1}{\sqrt{p}} (\hat{\mu}_0 - \hat{\mu}_1)^T H_{1-i}(\gamma_i) (\hat{\mu}_0 - \hat{\mu}_1), \ i \in \{0, 1\}$$

$$\hat{\delta}_i = \frac{1}{\gamma_i} \left[ \frac{p}{n_i} - \frac{1}{n_i} \text{Tr} [H_i(\gamma_i)] \right], \ i \in \{0, 1\}$$

$$\hat{b}_i = \frac{(-1)^i}{\sqrt{p}} \text{Tr} \left[ \Sigma_i H_{1-i}(\hat{\gamma}_{1-i}) \right] + \frac{(-1)^{i+1} n_i}{\sqrt{p}} \hat{\delta}_i, \ i \in \{0, 1\}$$

$$\hat{B}_1 = \left( 1 + \gamma_1 \hat{\delta}_1 \right)^4 \frac{1}{p} \text{Tr} \left[ \Sigma_1 H_1(\gamma_1) \Sigma_1 H_1(\gamma_1) \right] - \frac{n_1}{p} \left( \frac{1}{n_1} \text{Tr} [\Sigma_1 H_0(\gamma_0)] \right)^2 - 2 \left( 1 + \gamma_1 \hat{\delta}_1 \right)^2 \frac{1}{p} \text{Tr} \left[ \Sigma_1 H_1 H_0(\gamma_0) \right]$$

$$+ \hat{\delta}_1 \left( 1 + \gamma_1 \hat{\delta}_1 \right) \frac{2}{p} \text{Tr} \left[ \Sigma_1 H_0(\gamma_0) \right]$$

$$\hat{r}_i = \frac{1}{p} (\hat{\mu}_0 - \hat{\mu}_1)^T H_{1-i}(\hat{\gamma}_{1-i}) \Sigma_i H_{1-i}(\hat{\gamma}_{1-i}) (\hat{\mu}_0 - \hat{\mu}_1)$$

in the sense that:

$$\hat{\epsilon}_i - \epsilon_i^{R-QDA} \overset{a.s.}{\to} 0$$

It is worth noting that for $i=1$, $\gamma_i$ is replaced by $\hat{\gamma}_1$.

**Proof.** The proof of this theorem can be derived from the results established in Theorem 2 in (Elkhalil et al., 2017) and as such is omitted.
4. Numerical results

4.1 Validation with synthetic data

In this section, we assess the performance of our improved R-QDA classifier and compare it to the standard QDA classifier in the case of unbalanced data. To this end, we start by generating synthetic data for both classes that are compliant with the different assumptions used throughout this work in order to validate our theoretical results.

In Figure 2 and Figure 3, we plot the classification error rate of the improved classifier and the traditional R-QDA classifier with respect to the regularization parameter $\gamma_0$ and the features’ dimension $p$, respectively. As can be seen, we note that the standard R-QDA has a classification error rate that converges to the prior of the most dominant class, which reveals that as expected, it tends to assign all observations to the same class, which in this case coincides with the class that presents the highest number of training samples. On the opposite, the proposed R-QDA classifier presents a much higher performance, making it more suitable to cope with unbalanced settings. We finally note that the consistent estimator based on the results of Theorem 5 is accurate and as such can be used to properly adjust the regularization parameter $\gamma_0$.

4.2 Experiment with real data

In this section, we test the performance of the proposed R-QDA classifier on the public USPS dataset of handwritten digits (Lecun et al., 1998) and the EEG dataset. The USPS
Improved Design of Quadratic Discriminant Analysis Classifier in Unbalanced Settings

Figure 3: Average misclassification error rate versus the dimension $p$. We consider $\gamma = 1$ with unbalanced training size where $n_0 = 2n_1$, $[\Sigma_0] = 4I_p, \Sigma_1 = \Sigma_0 + 3Q_pD_pQ_p^T$, $Q_p \in O_n(R), D_p = \text{diag} \left[ 1_{\sqrt{p}}, 0_{(p - \sqrt{p})} \right]$ and $\mu_1 = \mu_0 + \frac{3}{\sqrt{p}}1_{p \times 1}$.

The dataset is composed of 42000 labeled digit images, and each image has $p = 784$ features represented by $28 \times 28$ pixels. The EEG dataset is composed of 5 classes that contain 4097 observations, and each observation has $p = 178$ features. We consider the classification of two classes from each dataset composed of $n_0$ and $n_1$ samples. Based on the results of Theorem 3, we tune the regularization factor $\gamma_0$ to the value that minimizes the consistent estimate of the misclassification error rate. The values of $\theta$ and $\hat{\gamma}_1$ are then computed based in (23) and (26). Fig. 4 and Fig.5 compares the performance of the proposed classifier with other state-of-the-art classification algorithms using cross-validation for different proportions of $n_0$ and $n_1$. As seen, our classifier, termed in the figure RQDA$^{\text{imp}}$, not only outperforms the standard QDA but also other existing classification algorithms. This suggests that the use of different regularization across classes in the QDA classification rule along with an adequate tune of the bias makes the QDA classifier more robust to the estimation noise of the covariance matrices in unbalanced settings.

5. Conclusion

A common belief holds that the use of R-QDA leads in general to lower classification performances than many other existing classification methods, even though it is a classifier derived from the maximum likelihood principle under a general Gaussian mixture model. As a matter of fact, contrary to the other existing classifiers, the main issues of the R-QDA lies in its high sensitivity to the estimation noise of the parameters of the Gaussian mixture model. Through a careful investigation of the classification rule of R-QDA, we prove that
in case of unbalanced training data, the estimation noise lead the R-QDA to assign all the observations to the same class, which is behind its inefficiency to classify data under such settings. In this work, we propose to modify the design of R-QDA so that it becomes more resilient to the estimation noise. Particularly, we propose to use two regularization parameters for each class as well as a carefully designed bias to optimize the classification performance. Our design, which leverages advanced results from random matrix theory,
clearly shows that there is room for improvement of basic classification methods based on the use of advanced statistical tools.

Appendix A.

As discussed in the paper, the design of the regularization parameters $\gamma_0$ and $\gamma_1$ should ensure that:

$$\frac{1}{\sqrt{p}} \text{Tr}\left[\Sigma_i (T_1 - T_0)\right] = O(1) \quad (27)$$

where $T_i = \left(I + \gamma_i \tilde{\delta}_i \Sigma_i\right)^{-1}$, with $\tilde{\delta}_i = \frac{1}{1+\gamma_i \delta_i}$. Using the relation $A^{-1} - B^{-1} = A^{-1}(B - A)B^{-1}$ for any two square matrices $A$ and $B$, (27) boils down to:

$$\frac{1}{\sqrt{p}} \text{Tr}\left[\Sigma_i T_1 \left(\gamma_0 \tilde{\delta}_0 \Sigma_0 - \gamma_1 \tilde{\delta}_1 \Sigma_1\right) T_0\right] = O(1)$$

or equivalently:

$$\frac{\gamma_0 \tilde{\delta}_0}{\sqrt{p}} \text{Tr}\left[\Sigma_i T_1 (\Sigma_0 - \Sigma_1) T_0\right] + \frac{\gamma_0 \tilde{\delta}_0 - \gamma_1 \tilde{\delta}_1}{\sqrt{p}} \text{Tr}\left[\Sigma_i T_1 \Sigma_1 T_0\right] = O(1)$$

Using Assumption 4, it can be readily seen that the first term $\frac{\gamma_0 \tilde{\delta}_0}{\sqrt{p}} \text{Tr}\left[\Sigma_i T_1 (\Sigma_0 - \Sigma_1) T_0\right] = \Theta(1)$. To satisfy (27), we thus only need to design $\gamma_0$ and $\gamma_1$ such that:

$$\gamma_0 \tilde{\delta}_0 - \gamma_1 \tilde{\delta}_1 = O(1/\sqrt{p})$$

or equivalently:

$$\gamma_0 + \frac{\gamma_0 \gamma_1}{n_1} \text{Tr}\left[\Sigma_i T_1\right] - \gamma_1 - \frac{\gamma_0 \gamma_1}{n_0} \text{Tr}\left[\Sigma_0 T_0\right] = \Theta(1/\sqrt{p})$$

Under Assumption 4,

$$\frac{1}{n_0} \text{Tr}\left[\Sigma_0 T_0\right] = \frac{1}{n_0} \text{Tr}\left[\Sigma_1 T_1\right] + O\left(\frac{1}{\sqrt{p}}\right)$$

which proves that in choosing $\gamma_1$ given by:

$$\gamma_1 = \frac{\gamma_0}{1 - \left(\frac{\frac{1}{n_1}}{\frac{1}{n_0}} - \frac{1}{n_0}\right) \gamma_0 \text{Tr}\left[\Sigma_0 T_0\right]}$$

the condition (27) becomes satisfied.

Appendix B.

The choice of the regularization parameters $\gamma_0$ and $\gamma_1$ allows to ensure that:

$$\overline{B}_0 = \overline{B}_1 + O\left(\frac{1}{\sqrt{p}}\right)$$

As a result, the expression of the asymptotic equivalents for the classification error rate of both classes defined in (15) for $i \in \{0,1\}$ can be reduced to:

$$\epsilon_i^{R-QDA} = - \Phi \left( -1 \cdot \frac{\overline{\Sigma}_i - \overline{B}_i}{\sqrt{2 \overline{B}_0}} \right) \frac{p}{n} \to 0 \quad (28)$$
Then, the total classification error can be written as:

$$\epsilon^{R\text{-}QDA} = \pi_0 \Phi \left( \frac{\beta_0 + \theta}{\alpha} \right) + \pi_1 \Phi \left( \frac{\beta_1 - \theta}{\alpha} \right)$$

where

$$\begin{align*}
\beta_0 &= \frac{1}{\sqrt{p}} \left[ -\mu^T T_1 \mu \right] - \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_0 (T_1 - T_0)] \\
\beta_1 &= \frac{1}{\sqrt{p}} \left[ -\mu^T T_0 \mu \right] + \frac{1}{\sqrt{p}} \text{Tr}[\Sigma_1 (T_1 - T_0)] \\
\alpha &= \sqrt{2B_0}
\end{align*}$$

Taking the derivative of this expression with respect to $\theta$ and setting it to zero, the optimal bias $\theta^*$ should satisfy:

$$\frac{\pi_0}{\pi_1} e^{\left( \frac{\beta_1 - \theta^*}{2\alpha} \right)^2 - \left( \frac{\beta_0 + \theta^*}{2\alpha} \right)^2} = 1$$

Applying the logarithmic function on both sides, we obtain:

$$\log \left( \frac{\pi_0}{\pi_1} \right) + \left( \frac{\beta_1 - \theta^*}{2\alpha} \right)^2 - \left( \frac{\beta_0 + \theta^*}{2\alpha} \right)^2 = 0$$

thus leading to

$$\theta^* = \frac{\beta_1 - \beta_0}{2} - \frac{2\alpha^2}{\beta_1 + \beta_0} \log \left( \frac{\pi_1}{\pi_0} \right)$$

**Appendix C**

In Theorem 4, we provide a consistent estimator for the regularization parameter $\gamma_1$ that satisfies (20) with high probability and a consistent estimator for the optimal bias $\theta^*$.

1. **Consistent estimator for $\gamma_1$**

   We start by proving that $\gamma_1 - \hat{\gamma}_1 \overset{a.s.}{\to} 0$. To this end, we need to provide a consistent estimator for $(\frac{1}{n_1} - \frac{1}{n_0}) \text{Tr}[\Sigma_0 T_0]$. We start by noticing that:

   $$\left( \frac{1}{n_1} - \frac{1}{n_0} \right) \text{Tr}[\Sigma_0 T_0] = \left( \frac{n_0}{n_1} - 1 \right) \delta_0$$

   A consistent estimator for $\delta_0$ has been provided in Elkhalil et al. (2017) and is given by:

   $$\hat{\delta}_0 = \frac{1}{\gamma_0} \frac{\frac{n_0}{n_0} - \frac{1}{n_0} \text{Tr}[H_0(\gamma_0)]}{1 - \frac{\gamma_0}{n_1} + \frac{1}{n_0} \text{Tr}[H_0(\gamma_0)]}$$

   and as such a consistent estimator for $\gamma_1$ in (21) is given by:

   $$\hat{\gamma}_1 = \frac{\gamma_0}{1 - \gamma_0 (\frac{n_0}{n_1} \delta_0 - \delta_0)}$$

   Note that the replacement of $\gamma_1$ by $\hat{\gamma}_1$ still ensures condition (27) since from standard results of random matrix theory $\delta_0 - \delta_0 = O(\frac{1}{\beta})$ with high probability.
.2 Consistent estimator for $\theta^*$

Recall that

$$
\theta^* = \frac{\beta_1 - \beta_0}{2} - \frac{2\alpha^2}{\beta_1 + \beta_0} \log(\frac{\pi_1}{\pi_0})
$$

To provide a consistent estimator for $\theta^*$, it is thus required to provide that of $\beta_0, \beta_1$ and $\alpha$. Since $\alpha = \sqrt{2B_0}$ and $\hat{B}_0 - B_0 \overset{a.s.}{\rightarrow} 0$, we thus have: $\hat{\alpha} - \alpha \overset{a.s.}{\rightarrow} 0$ where $\hat{\alpha} = \sqrt{2B_0}$. As for $\beta_i$, $i = 0, 1$, it can be written as:

$$
\beta_i = -\frac{1}{\sqrt{p}} \mu^T Y_i - i \mu + \frac{1}{\sqrt{p}} \text{Tr} [\Sigma_i Y_i] - \frac{1}{\sqrt{p}} \text{Tr} [\Sigma_i Y_{1-i}]
$$

$$
= -\frac{1}{\sqrt{p}} \mu^T Y_{1-i} - i \mu - \frac{1}{\sqrt{p}} \text{Tr} [\Sigma_i Y_{1-i}] + \frac{n_i}{\sqrt{p}} \delta_i
$$

Due to the independence of $\Sigma_i$ from $H_{1-i}$ and of $\hat{\mu}_1$ and $\hat{\mu}_0$ and $H_i$, $i = 0, 1$, we have:

$$
\frac{1}{\sqrt{p}} \text{Tr} [\hat{\Sigma}_i H_{1-i}] - \frac{1}{\sqrt{p}} \text{Tr} [\Sigma_i Y_{1-i}] \overset{a.s.}{\rightarrow} 0
$$

and

$$
\frac{1}{\sqrt{p}} (\hat{\mu}_0 - \hat{\mu}_1) H_{1-i} (\hat{\mu}_0 - \hat{\mu}_1) - \frac{1}{\sqrt{p}} (\hat{\mu}_0 - \hat{\mu}_1) T_{1-i} (\hat{\mu}_0 - \hat{\mu}_1) \overset{a.s.}{\rightarrow} 0.
$$
