(Dated: June 1, 2023)

The time-evolution of multi-neutrino entanglement and correlations are studied in two-flavor collective neutrino oscillations, relevant for dense neutrino environments, building upon previous work. Specifically, simulations performed of systems with up to 12 neutrinos using Quantumum’s H1-1 20 qubit trapped-ion quantum computer are used to compute n-tangles, and two- and three-body correlations, probing beyond mean-field descriptions. n-tangle re-scalings are found to converge for large system sizes, signaling the presence of genuine multi-neutrino entanglement.

In extreme astrophysical environments, such as those found in core-collapse supernovae, neutrino densities are sufficiently high to participate in the transport of energy and momentum, in local chemical compositions and in dynamics [1-5]. Coherent evolution of lepton flavors, that depends on self-interactions between neutrinos induced by weak interactions [6-10], plays an important role. First studies of the quantum correlations in coherent evolution of dense neutrino systems, beyond mean-field descriptions, are providing important insights into such dynamics [11-28]. So far, they have focused on bipartite entanglement witnesses, such as entanglement entropy, negativity and concurrence [15-19, 21-26]. In this work, we explore multi-neutrino entanglement in such systems by computing n-tangles [29], \( \tau_n \), between \( n \) neutrinos induced by time evolution. The total \( n \)-tangles at late times are found to scale for large system sizes. Our work utilized classical simulations, and quantum simulations using the Quantumum 20-qubit trapped-ion quantum computer H1-1 and noisy emulator H1-1E [30].

The leading-order low-energy effective Hamiltonian describing collective, coherent neutrino flavor oscillations is composed of three terms. One term is responsible for vacuum oscillations, originating from the neutrino mass matrix [31-34]. A second is from the weak interactions between neutrinos and matter, mainly between \( \nu_e \) and \( e^- \), through charged-current processes, and is responsible for the Mikheev-Smirnov-Wolfenstein effect [35, 36]. In what follows, we neglect the contributions from this term. A third term, from the neutral-current weak interactions, is responsible for coherent forward scattering of neutrinos, which becomes significant at sufficiently high neutrino densities [7-10].

Due to the small value of \( \theta_{13} \) [37], three-flavor neutrino systems can be approximated by two-flavor systems involving the electron neutrino \( \nu_e \) and a heavy neutrino \( \nu_x \), considered to be a combination of \( \nu_x \) and \( \nu_x \) [38]. The effective Hamiltonian for \( N \) neutrinos can be written in terms of spin operators acting in flavor space [14],

\[
H = H' + H'' = \sum_i b \cdot \sigma^{(i)} + \frac{1}{2N} \sum_{i<j} J_{ij} \sigma^{(i)} \cdot \sigma^{(j)},
\]

where \( \sigma^{(i)} = (\sigma^{(i)}_x, \sigma^{(i)}_y, \sigma^{(i)}_z) \) are the Pauli matrices acting on the \( i \)-th neutrino flavor-doublet, \( (|\nu_e \rangle, |\nu_x \rangle)^T \). The 3-vector \( b \) encodes the vacuum oscillations,

\[
b = \frac{\Delta m^2}{4E} \left( \sin(2\theta_e), 0, -\cos(2\theta_e) \right),
\]

with \( \Delta m^2 \) being the difference between neutrino squared-masses, \( E \) the neutrino energy, and \( \theta_e \) the vacuum-mixing angle. The two-body couplings \( J_{ij} \), uniquely defined at leading order by the Standard Model, are,

\[
J_{ij} = \sqrt{2} G_F \rho_\nu \left( 1 - \cos \theta_{ij} \right),
\]

where \( G_F \) is Fermi’s constant, \( \rho_\nu \) the number-density of neutrinos, and \( \theta_{ij} \) the angle of the momenta between the \( i \)-th and \( j \)-th neutrino. Following previous works, e.g., Refs. [18, 28], we introduce \( \mu \equiv \sqrt{2} G_F \rho_\nu \), and, for demonstrative purposes, set \( \mu/N = \Delta m^2/4E \) (assuming a monochromatic beam), so that the one- and two-body terms have comparable strengths [18]. Following the inspiring work of Hall et al. [18], a one-parameter set is used to demonstrate relevant physics, with a vacuum-mixing angle of \( \theta_e = 0.195 \), a distribution of momenta with \( \theta_{ij} = \arccos(0.9) \times |i - j|/(N - 1) \) (cone-shaped), and an initial state that is a product state of \( N/2 \langle \nu_e \rangle \) and \( N/2 \langle \nu_x \rangle \), i.e., \( |\Psi_0 \rangle = |\nu_e \rangle \otimes |\nu_x \rangle \otimes |\nu_x \rangle \).

While a number of previous calculations of neutrino systems using quantum devices have been focused on the coherent time evolution of the flavor content [18, 20, 25, 28], and the entanglement of one or two neutrinos, here we examine correlations between different neutrinos and multi-body entanglement, quantities that can further probe mean-field descriptions of these systems. Specifically, we look at the two-body correlations, as considered previously, e.g., Ref. [26],

\[
C_{ij}^{(2\nu)}(t) = \langle \sigma^{(i)}_z \sigma^{(j)}_z \rangle - \langle \sigma^{(i)}_z \rangle \langle \sigma^{(j)}_z \rangle, \quad i \neq j,
\]

with \( \langle \cdot \rangle = \langle \Psi_t | \cdot | \Psi_t \rangle \), and three-body correlations,

\[
C_{ijk}^{(3\nu)}(t) = \langle \sigma^{(i)}_z \sigma^{(j)}_z \sigma^{(k)}_z \rangle - \langle \sigma^{(i)}_z \rangle \langle \sigma^{(j)}_z \rangle \langle \sigma^{(k)}_z \rangle
+ 2 \langle \sigma^{(i)}_z \rangle \langle \sigma^{(j)}_z \rangle \langle \sigma^{(k)}_z \rangle, \quad i \neq j \neq k.
\]
Ultimately, studies of entanglement will help quantify the limitations of classical techniques in providing reliable and accurate results, and can also guide tensor-networks approaches \[17, 19, 24\]. Entanglement in neutrino systems has been previously computed via full-state tomography \[18, 25\], which, however, is expected to become inefficient for larger systems due to the required number of measurements. Alternative methods including classical shadows \[39\], which are expected to require fewer measurements. Alternative methods including classical shadows \[39\], which are expected to require fewer measurements.

As a way to gain further insight into the entanglement structure of dense, coherent neutrino systems, we focus on the \( n \)-tangle \( \tau_n \), defined as \( \| \langle \Psi | \sigma^{\otimes n} | \Psi \rangle \|^2 \), where \( | \Psi \rangle \) is the complex conjugate of \( | \Psi \rangle \). This quantity is a measure of the \( n \)-body entanglement \[29\]. For two-qubit (neutrin) systems, \( \tau_2 \) is the concurrence squared \[40, 41\], \( C_{21}^2 \). For three-qubit systems, \( \tau_3 \) is the residual entanglement \[42\], \( C_{1(23)}^2 - C_{12}^2 - C_{13}^2 \), with \( C_{1(23)} = \sqrt{2 - 2 \text{Tr} \rho_1^2} \), with \( \rho_1 \) the reduced density matrix of the first qubit. However, for \( n \geq 4 \), \( \tau_n \) is not uniquely the residual entanglement, and it is smaller than or equal to the concurrence \( C_{1(2...n)} \) \[43\]. An interesting property of \( \tau_n \) is, that, for the \( N \)-qubit GHZ state \[44, 45\], \( \tau_N = 1 \), while for the \( N \)-qubit W state \[46\], \( \tau_N = 0 \). Thus, while it can help distinguish between different types of entanglement, by itself it is not a measure of \( N \)-body entanglement \[29\].

**Implementation on a Quantum Computer** — Previous works have performed quantum simulations of these systems using IBM’s superconducting-qubit quantum computers \[18, 20\], D-Wave’s superconducting-qubit annealing devices \[25\] and Quantumum’s Trapped-ion quantum computers \[28\]. We implement the time evolution of an initial state \( \Psi_0 \) under the Hamiltonian given in Eq. (1) using Quantumum’s H1-1 20 qubit trapped-ion quantum computer, that is based on using the two hyperfine clock states in the \( ^2S_{1/2} \) ground state of \(^{172}\)Yb\(^+\) ions as qubits \[30\]. For purposes of comparison, we also provide results obtained using its emulator, H1-1E.\(^2\) The evolution operator, \( \exp(-iHt) \), is Trotterized, and each contribution is mapped to a quantum circuit composed of gates that are native to H1-1. As noted in Ref. \[28\], the one-body and two-body parts of the Hamiltonian commute, \( [H^\rho, H^{\rho\nu}] = 0 \), so they can be Trotterized without introducing a higher-order systematic error. For \( H^\rho \),

\[ e^{-itH^\rho} = \bigotimes_i e^{-i\theta_i \sigma^{(i)}_{\alpha}}. \]  

This term is implemented with the following Euler decomposition for \( SU(2) \) matrices \[50\],

\[ e^{-i\theta_i \sigma^{(i)}_{\alpha}} = \begin{pmatrix} R_x(\alpha_1) & 0 \\ 0 & R_y(\alpha_2) \end{pmatrix} R_z(\alpha_3), \]  

where the angles \( \alpha_i \) are fixed numerically.

For \( H^{\nu\nu} \), the known decomposition of \( SU(4) \) matrices with 3 CNOT gates \[51\] is used,

\[ e^{-i\theta_{ij} \sigma^{(i)}_{\alpha} \sigma^{(j)}_{\beta}} = \begin{pmatrix} R_z(\beta - \frac{\pi}{2}) & 0 \\ 0 & R_z(\beta - \frac{\pi}{2}) \end{pmatrix}, \]  

with \( \beta = 2\theta_{ij} \), which has a slight advantage over \[52, 53\] (requiring 5 single-qubits gates instead of 8). While not directly relevant to the present set of simulation, it is interesting to consider the T-gate resource requirements for such simulation. Standard methods\(^3\) suggest a T-gate count of \( N(187N - 101)/2 \) for \( \epsilon = 10^{-4} \), for \( N \) neutrinos per Trotter step. While the circuits in Eqs. (7) and (8) are not written in terms of the native gates used in H1-1 (these can be found in Ref. \[28\]), the package pytket \[58\] includes a function that performs this translation, along with optimizations. Implementation of this two-neutrino term is more delicate. Since the sum over different pairs of neutrinos is split in the implementation of the time-evolution operator, the non-commutativity of terms introduces systematic Trotter errors. While it is possible

\(^1\) There are other ways to ascertain the nature of entanglement in these systems. For example, a more complete set of two-point correlation functions could be used to determine the Quantum Fisher information, \( F = \sum_{\alpha, \beta} \sum_{i, j} n_i n_j C_{i, \alpha, j, \beta}^\dagger C_{i, \beta, j, \alpha} \), with \( n_i \) being unit vectors and \( C_{i, \alpha, j, \beta} = (\sigma^{(i)}_{\alpha}) (\sigma^{(j)}_{\beta}) - (\sigma^{(i)}_{\beta}) (\sigma^{(j)}_{\alpha}) \), which can be used to learn about the nature of entanglement \[47, 48\].

\(^2\) Ref. \[49\] showed that H1-1E could well reproduce the behavior of H1-1.

\(^3\) Following Ref. \[54\], and assuming no additional ancilla qubits are used, for general single-qubit rotations \( U_1 \), Refs. \[55, 56\] give the following estimates of the number of T-gates, \( T_{U_1}(\epsilon) = 2.95 \log_2(1/\epsilon) + 3.75 \). For \( R_z \), Ref. \[57\] gives \( T_{R_z}(\epsilon) = 3.21 \log_2(1/\epsilon) - 6.93 \).

FIG. 1. Circuits for a single Trotter step for (a) \( N = 4 \), (b) \( N = 6 \), (c) \( N = 8 \), and (d) \( N = 12 \) neutrinos, where the two-neutrino gates are clustered into groups that can be applied in parallel, showing the linear scaling with \( N \) of the circuit depth.
to find a combination that minimizes this error, as in Ref. [28] for the case of 4 neutrinos, this is not feasible for larger systems. As shown in Ref. [18], it is possible to build a circuit that performs the Trotterized version of \( \exp(-itH^{νν}) \) with \( N \) layers of the operator in Eq. (8) (if multiple gates can be applied in parallel across the device). Figure 1 shows the circuits used for different number of neutrinos. A nice property of these circuits is that they retain the symmetry present in the Hamiltonian given in Eq. (1), between the exchange of the \( i^{\text{th}} \) and \( (N - i + 1)^{\text{th}} \) neutrino, for the current choice of \( J_{kj} \).

While first order Trotter evolution has been used, higher orders with their improved convergence have been explored in Ref. [28]. They found that the Trotter errors from first and second order evolution from the prepared initial state are significantly smaller than naive theoretical bounds. Alternative methods for time evolution, such as Variational Fast Forwarding [59], should also be examined.

Two- and Three-Neutrino Correlations — A term that appears in the computation of correlation functions is the expectation value of \( σ_z \). For this reason, it is interesting to first compute the inversion probability for a single neutrino, defined as

\[
P_i(t) = \frac{1}{2}(1 \mp \langle σ_z^{(i)} \rangle),
\]

where the \( \mp \) sign depends on the initial state of the \( i^{\text{th}} \) neutrino (\( − \) for \( ν_e \) and \( + \) for \( ν_x \)). Due to the symmetry of the Hamiltonian (and its Trotterized version), the inversion probabilities for the \( i^{\text{th}} \) and \( (N - i + 1)^{\text{th}} \) neutrino are the same. The results for \( N = 12 \) are shown in Fig. 2, where the two icons in the legend indicate whether a quantum device (blue) or emulator (yellow) was used to obtain the results [60], and the \( N = 8 \) are in the Supplemental Material (SM). The uncertainties in the results are computed via bootstrap resampling. For the \( N = 8 \) case, agreement is found with the results presented in Ref. [28]. For \( N = 12 \), both results from H1-1 and H1-1E are showing somewhat larger deviations from expectations, but the device has remained coherent.

As a selection of two- and three-body correlations, we focus on

\[
C_{1i}^{(2ν)}, \text{ with } 1 < i \leq N, \quad C_{1i}^{(3ν)}, \text{ with } 1 < i < N,
\]

\[
C_{i,i+1}^{(2ν)}, \text{ with } 1 \leq i < N, \quad C_{i-1,i,i+1}^{(3ν)}, \text{ with } 1 < i < N.
\]

A representative set of correlation functions for \( N = 12 \) neutrinos is shown in Fig. 3, and a more complete set can be found in the SM. For the two-body correlations, results from H1-1 and H1-1E follow the expected values, although somewhat limited by statistics. This gets more prominent when looking at the three-body correlations, where with the current uncertainties most of the points are consistent with zero. As seen by comparing the results from H1-1 and H1-1E, increasing the accumulated statistics by factor of 5 makes a substantial difference, but it remains insufficient. Increasing further the number of shots would help resolve those small values, which would be reasonable with, for instance, IBM’s quantum computers (where usually one works with \( \gtrsim 10^3 \) shots). With the possibility of performing more shots, error mitigation techniques, such as randomized compiling [61] and decoherence renormalization [62–64], become viable. While these correlations differ from zero, with a hierarchy \( C^{(2ν)} > C^{(3ν)} \), an interesting trend is that \( C_{1i}^{(2ν)} \) plateaus

The associated SM gives the numerical values of the results shown in Fig. 2, and those shown in subsequent figures.
at late times, with $C_{12}^{(2n)}$ reaching a value $\sim 0.5$, down to $\sim -0.5$ for $C_{12}^{(2\nu)}$. Other limiting patterns are not found for other computed quantities.

A potential improvement to the current results has been explored, in which a post-selection of the counts that satisfy the symmetries of the Hamiltonian. This technique has been used with great success when studying quantum field theories, e.g., see Refs. [49, 64–66]. However, specific to this system in the flavor basis, $b \cdot J$ is the conserved quantity (and not $J_z$), which makes post-selection not feasible in our studies.²

Multi-Neutrino Entanglement — The $N$-tangle, $\tau_N$, is an interesting measure of multi-neutrino entanglement in these systems which is straightforward to compute via,

$$\tau_N(t) = \frac{\langle \Psi_t | \sigma_y^\otimes N | \Psi_t \rangle^2}{\langle \Psi_0 | e^{i t H} \sigma_y^\otimes N e^{i t H} | \Psi_0 \rangle^2},$$

(10)

(without the need to use the SWAP test [67–69] to compute the overlap). We have performed such calculations for the system of $N = 4$ neutrinos using $H_{1-1}$ and $H_{1-1E}$, as shown in the top panel of Fig. 4, where two Trotter steps have been used in applying $e^{itH}$. The $N = 6$ system has also been studied, but only using $H_{1-1E}$ (and with a single Trotter step). For the time-range displayed, $\tau_N$ is seen to decrease rapidly with system size.

To further explore the dependence of multi-neutrino entanglement with system size, it is interesting to look at $\tau_n$, with $n < N$. For this quantity, a re-scaling of the sum of the $\tau_{n,8}$ is found to be helpful,

$$\tilde{\tau}_{n,N} = \frac{1}{N^{n-2}} \sum_i \tau_n^{(i)},$$

(11)

where the index $i$ in $\tau_n^{(i)}$ identifies one of the possible $\binom{N}{n}$ permutations of $\sigma_y^\otimes n$. Figure 5 shows the re-scaled $\tilde{\tau}_{n,N}$ for different values of $N$ and $n$. These quantities are seen to exhibit convergence to a fixed curve with increasing $N$, starting for relatively small system sizes. The time required to reach the plateau region increases with $n$, consistent with the notion that more time is required to entangle $n$ neutrinos than $n - 1$. Moreover, upon further investigation, these plateaus are found to be robust against variations of the two-body coupling strength (increasing or decreasing the angle of the cone) and vacuum-mixing angle (more or less oscillatory behavior), the only observed difference is in the relaxation time (shorter times for wider cones because the interaction strength $J_{ij}$ is stronger).

While this scaling is somewhat puzzling, it can be compared to other entangled multiqubit systems, for which analytic results are available. For example, the GHZ state has $\tau_{n=N} = 1$ and $\tau_{n<N} = 0$, while the W state has $\tau_n = 0$ for $n < N$. A system that has similar scaling is the product of $N/2$ Bell pairs, with $\tau_n = \binom{N/2}{n} \sim N^{n/2}$. Comparing this with the scaling from Eq. (11), the $n$-tangle grows faster for the neutrino state than the Bell-pairs-state with system size (except for $t_2$ and $t_1$), as depicted in Fig. 6. This implies that there is multi-neutrino entanglement, beyond the two-neutrino entanglement found in the $(N/2)$-product Bell-pairs-state.

The present analysis concerns the coherent flavor oscillations of a mono-energetic neutrino gas starting in a mixed-flavor pure state. To gain an understanding of such dynamics in a mixed state, we have also examined

---

² Calculations could be performed in the mass basis, but the selected initial state would then be a sum of product states, which would complicate the calculation of the $n$-tangle.

⁶ e.g., for $N = 4$ and $n = 2$, these are $\sigma_y^\otimes \sigma_y^\otimes I^\otimes I$, $\sigma_y^\otimes I^\otimes \sigma_y^\otimes I$, ....
the impact of different initial states for the evolution, and find that the values of $n$-tangle depend upon the initial state in non-trivial ways. A mono-flavor initial state gives vanishing $n$-tangle, while an initial state with a single distinct flavor has non-zero 2-tangle, resembling a W-state (the oscillations are too large to discriminate between the different $N$-scalings, consistent with $2(N - 1)/N$ or $N^{n-2}$). Gases of different energy neutrinos can be described within this framework through different values of $b$ in Eq. (2).

**Summary and Conclusions** — The time evolution of multi-neutrino quantum correlations and entanglement in dense neutrino systems is studied for systems of $N = 1$, 2, 4, 6, 8 and 12 neutrinos using Quantumult's H1-1 20 qubit trapped ion quantum computer and its associated noisy emulator H1-1E. The central reason for including and developing methods for implementation on quantum computers is that determining the entanglement of the larger systems that will be required as input into realistic astrophysical simulations will need quantum simulations of such systems with larger numbers of neutrinos (than in this work). We have chosen to study the $n$-tangle in order to provide insight into the multi-particle entanglement structure of the systems. Compared to other entanglement witnesses, the $n$-tangle is straightforward to compute using a quantum computer (at least for a single product state, as considered here), since it does not require state tomography. The behavior of re-scaled sums over $n$-tangles are found to converge to universal curves with increasing system sizes, that depend upon the parameters of the Hamiltonian, with late-time plateaus. Further, the magnitudes of the $n$-tangles are found to increasingly exceed that of systems comprised of neutrino Bell-pairs, indicating the presence of genuine multi-neutrino entanglement in collective coherent neutrino flavor oscillations in dense systems.

SUPPLEMENTARY MATERIAL
MULTI-NEUTRINO ENTANGLEMENT AND CORRELATIONS IN DENSE NEUTRINO SYSTEMS

This supplementary material contains additional figures and the tabulated results obtained with quantum simulations using Quantinuum’s 20 trapped-ion quantum computer H1-1, its noisy emulator H1-1E, and other classical simulations, used to produce the figures. In the legend of the figures, “Exact” results are obtained by computing the exponentiation of the Hamiltonian with Mathematica [70], except for the results for the n-tangle in Fig. 5, where Julia [75] was used (with its Expokit package [76]). The “Trotter” results were obtained with Mathematica also, by first identifying the different terms in the Hamiltonian that can be implemented together (mainly, those shown in Eqs. (7) and (8)), exponentiating them separately, and multiplying them in the order used in the quantum circuits (as a check, this was compared with the results obtained with the qiskit noiseless simulator [78] using the quantum circuits run on H1-1).

FIG. S1. Flavor inversion probabilities for systems with \( N = 8 \) (left) and \( N = 12 \) (right) neutrinos. The lines show the single-step Trotter (continuous) and exact (dashed) simulations, and the points show the results from H1-1 (dark circles, using 240 shots) and H1-1E (light squares, using 1200 shots).
