ABSTRACT

We present results from X-ray observations of the gravitationally lensed $z = 1.51$ active galactic nucleus (AGN) HS 0810+2554 performed with the Chandra X-ray Observatory and XMM-Newton. Blueshifted absorption lines are detected in both observations at rest-frame energies ranging between ~1 and 12 keV at $\geq$99% confidence. The inferred velocities of the outflowing components range between $\sim$0.1c and $\sim$0.4c. A strong emission line at $\sim$6.8 keV that is accompanied by a significant absorption line at $\sim$7.8 keV is also detected in the Chandra observation. The presence of these lines is a characteristic feature of a P-Cygni profile supporting the presence of an expanding, outflowing, highly ionized iron absorber in this quasar. Modeling of the P-Cygni profile constrains the covering factor of the wind to be $\geq$0.6, assuming disk shielding. A disk-reflection component is detected in the XMM-Newton observation accompanied by blueshifted absorption lines. The XMM-Newton observation constrains the inclination angle to be $<45^\circ$ at 90% confidence, assuming that the hard excess is due to blurred reflection from the accretion disc. The detection of an ultrafast and wide-angle wind in an AGN with intrinsic narrow absorption lines (NALs) would suggest that quasar winds may couple efficiently with the intergalactic medium and provide significant feedback if ubiquitous in all NAL and broad absorption line (BAL) quasars. We estimate the mass-outflow rate of the absorbers to lie in the range of $1.5$–$3.4 \times 10^3 M_{\odot}$ yr$^{-1}$ for the two observations. We find that the fraction of kinetic to electromagnetic luminosity released by HS 0810+2554 is large ($\epsilon_K = 9^{+8}_{-5}$), which suggests that magnetic driving is likely a significant contributor to the acceleration of this outflow.

Key words: galaxies: evolution – galaxies: formation – intergalactic medium – quasars: absorption lines – X-rays: galaxies

1. INTRODUCTION

Our X-ray survey of narrow absorption line (NAL; FWHM $\leq 500$ km s$^{-1}$) active galactic nuclei (AGNs) with outflows (Chartas et al. 2009) has revealed a remarkable X-ray bright, gravitationally lensed object: HS 0810+2554. It was detected in a 5 ks Chandra observation with a 2–10 keV observed flux of $8 \times 10^{-13}$ erg s$^{-1}$ cm$^{-2}$ and its spectrum shows hints of blueshifted high-energy broad absorption lines (BALs) implying the presence of a massive and ultrafast X-ray absorbing wind (Chartas et al. 2014). The Very Large Telescope (VLT/UVES) spectrum of HS 0810+2554 shows blueshifted C iv and N v doublets that are likely intrinsic to the quasar outflow based on a partial covering analysis (see Chartas et al. 2014 and references therein). The observed wavelengths of the C iv doublet ($\lambda \lambda 1548.20$, $1550.77$ Å) imply that the UV absorber is outflowing with a speed of $v_{c_4} \sim 19,400$ km s$^{-1}$. The only other quasar detected to date with similar blueshifted X-ray absorption features and an NAL outflow is the unlensed $z = 2.74$ NAL quasar HS 1700+6414 (Lanzuisi et al. 2012), which, however, has a $\sim$10 times lower 2–10 keV flux of $3.9 \times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$.

Blueshifted X-ray broad absorption lines have been detected in several high-z quasars (i.e., APM 08279+5255, Chartas et al. 2002; PG 1115+080, Chartas et al. 2003; and HS 1700+6416, Lanzuisi et al. 2012). Our spectral analysis of the 5 ks Chandra observation also revealed a possible near-relativistic outflow of X-ray absorbing material in HS 0810+2554 (Chartas et al. 2014). Because of the low signal-to-noise ratio (S/N) of the 5 ks Chandra observation, only the combined spectrum of all of the images was analyzed. The main result from that analysis was the detection of absorption lines at rest-frame energies of $\sim$7.7 keV and $\sim$10 keV at the 97% significance level, implying the presence of two outflowing components at velocities of $\sim$0.13c and $\sim$0.41c, respectively.

We recently re-observed HS 0810+2554 for $\sim$98 ks with Chandra and for $\sim$46.4 ks with XMM-Newton. The goals of the follow-up observations of HS 0810+2554 were the following: (a) to confirm the ultrafast outflow of HS 0810+2554 at different epochs and in individual images, (b) to constrain the properties of the outflowing material in the higher S/N observations, (c) to study the variability of the X-ray outflow, and (d) to determine the contribution of a galaxy group to the lensing of HS 0810+2554. In this paper, we present the results from these observations of HS 0810+2554 and address the science goals that we set out to meet.

In Section 2, we present the spectral and spatial analysis of HS 0810+2554 and a nearby galaxy group that contributes to the lensing. In Section 3, we discuss the properties of the outflow and how our estimated values of the mass-outflow rate, wind efficiency, and covering factor imply that the quasar wind in HS 0810+2554 provides significant feedback through a massive, energetic, and wide-angle outflow. Finally, in Section 4, we present a summary of our conclusions. Throughout this paper, we adopt a flat $\Lambda$ cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.3$, and $\Omega_{\Lambda} = 0.7$. The cross section of the Solar System is $1.8 \times 10^{-24}$ cm$^2$.

Chartas et al.

\( H_0 = 67 \text{ km s}^{-1} \text{Mpc}^{-1}, \Omega_\Lambda = 0.69, \) and \( \Omega_M = 0.31 \), based on the Planck 2015 results (Planck Collaboration et al. 2015).

2. X-RAY OBSERVATION AND DATA ANALYSIS

HS 0810+2554 was observed with the Advanced CCD Imaging Spectrometer (ACIS; Garmire et al. 2003) on board the Chandra X-ray Observatory (hereafter Chandra) on 2002 January 30 and 2013 December 16 with effective exposure times of 4894 s and 97,730 s, respectively. HS 0810+2554 was also observed with XMM-Newton (Jansen et al. 2001) on 2014 October 4 with an effective exposure of 46,400 s. The analysis of the 2002 observation was presented in Chartas et al. (2014). Here, we describe the analysis of the 2013 and 2014 observations of HS 0810+2554.

For the reduction of the Chandra observations, we used the CIAO 4.6 software with CALDB version 4.5.9 provided by the Chandra X-ray Center (CXC). We used standard CXC threads to screen the data for status, grade, and time intervals of acceptable aspect solution and background levels. To improve the spatial resolution, we employed the sub-pixel resolution technique developed by Li et al. (2004) and incorporated via the Energy-Dependent Subpixel Event Repositioning algorithm into the tool acis_process_events of CIAO 4.5. The pointing of the telescope placed HS 0810+2554 on the back-illuminated S3 chip of ACIS.

For the reduction of the XMM-Newton observations, we filtered the pn (Strüder et al. 2001) and MOS (Turner et al. 2001) data by selecting events corresponding to the instrument patterns in the 0–4 (single and double pixel events) and 0–12 (up to quadruple pixel events) ranges, respectively. Several moderate-amplitude background flares were present during the last \( \sim 7 \) ks of the XMM-Newton observation of HS 0810+2554. The pn and MOS data were filtered to exclude times when the full field-of-view count rates exceeded 30 cnts s\(^{-1}\) and 4 cnts s\(^{-1}\), respectively.

To test the sensitivity of our results to background flares, we also extracted pn and MOS spectra with more conservative values of the full field-of-view count rates of 20 cnts s\(^{-1}\) and 3 cnts s\(^{-1}\), respectively. To test for sensitivity to background non-uniformity, we also tried different background extraction regions. We did not find any differences in the spectral shapes and features using the more conservative threshold cuts or selecting different background extraction regions.

The pn and MOS spectra were fit with a variety of models employing XSPEC version 12 (Arnaud 1996). The energy ranges used for fitting the pn and MOS data were 0.3–11 keV and 0.4–10 keV, respectively. We performed spectral fits to the pn spectra alone and to the pn and MOS data simultaneously. Both approaches resulted in values for the fitted parameters that were consistent within the errors, however, the fits to the higher-quality pn data alone yielded lower reduced \( \chi^2 \) values compared to the combined fits. We therefore consider the results from the fits to the pn data alone to be more reliable, especially for characterizing the properties of the X-ray absorption features.

The Chandra spectra of the individual images of HS 0810+2554 were also fit with a variety of models employing XSPEC. For all of the spectral models of HS 0810+2554, we included Galactic absorption due to neutral gas (Dickey & Lockman 1990) with a column density of \( N_H = 3.94 \times 10^{20} \text{ cm}^{-2} \).

2.1. Spatial Analysis of HS 0810+2554

We perform a spatial analysis of the Chandra observation of HS 0810+2554 by fitting the lensed images (see Figure 1) simultaneously using the relative astrometry derived from Hubble Space Telescope (HST) images and MARX models (Wise et al. 1997) of the point-spread function (PSF). The details of this analysis are similar to the procedure described in Chartas et al. (2014). Table 1 lists the observation date, the observational identification number, the exposure time, and the number of counts (in the 0.2–10 keV band) of each image corrected for PSF effects. For comparison, we also include the results from the 2002 observation of HS 0810+2554. The total 0.2–10 keV count-rate has decreased by a factor of \( \sim 2.5 \) between the 2003 and 2013 epochs. XMM-Newton does not resolve the lensed images of HS 0810+2554, and in Table 1 we list the total background-subtracted EPIC-pn counts from all of the images.

Figure 1 shows a binned image and the best-fit PSF model of the 2013 Chandra observation of HS 0810+2554. In Figure 2, we show the deconvolved image. For the deconvolution, we applied the Richardson–Lucy algorithm (Richardson 1972; Lucy 1974) and supplied a PSF created by the simulation tool MARX (Wise et al. 1997). Images A and B are not resolved, while image C is resolved in the deconvolution. Image D is likely too faint to be reconstructed in the deconvolution.
The multi-wavelength flux ratios of HS 0810+2554 are presented in Table 2. Image C is significantly brighter in the X-ray band in the 2013 epoch compared to the 2002 epoch and its X-ray flux ratio differs significantly from the optical. Images C and D are easily resolved by Chandra and HST and their flux ratios are less affected by any possible systematic effects due to PSF modeling. One possible explanation of this flux anomaly of image C is strong magnification due to microlensing of this image during the 2013 observation. Microlensing will generally distort the X-ray spectrum of the affected image. We therefore fit the Chandra spectra of images (A+B) and C separately (see Section 2.2.1).

2.2. Spectral Reduction Procedures of HS 0810+2554

For the spectral analysis of the Chandra observations, we extracted spectra for the combined images A+B and for the spatially resolved image C. Image D was too faint to extract a spectrum. The extracted regions are shown in Figure 1. The background were determined by extracting events within an annulus centered on the mean location of the images with inner and outer radii of 10 arcsec and 50 arcsec, respectively. The extracted Chandra spectra were grouped to obtain a minimum of 20 counts in each energy bin, which is above the minimum required number of counts per bin for $\chi^2$ to be statistically valid (e.g., Cash 1979; Bevington & Robinson 2003).

For the spectral analysis of the XMM-Newton observation, we extracted spectra for the combined A+B+C+D images. The extracted spectra from the pn and MOS were grouped to obtain a minimum of 40 counts in each energy bin, allowing the use of $\chi^2$ statistics. We tested the sensitivity of our results to the grouping factor by performing the analysis with the grouping ranging between 20 counts per bin and 100 counts per bin. The best-fit parameters were found to be similar in all of the cases. We selected a grouping of 40 counts per bin because this provided tight constraints on the fitted parameters, with the bin size being comparable to or smaller than the energy resolution of the instrument in regions of the spectrum where we expect to find narrow absorption or emission lines. Background spectra for the pn and MOS detectors were extracted from source-free regions near HS 0810+2554.

We performed fits to the spectra of HS 0810+2554 with a variety of models of increasing complexity. The fit residuals show significant absorption and/or emission at observed-frame energies of 1–8 keV. To illustrate the presence of these features, we fit the Chandra spectra of combined images A+B and resolved image C (see Figure 3) and the XMM-Newton spectra of combined A+B+C+D images (see Figure 4) in the observed-frame 0.35–10 keV band with a power-law model (modified by Galactic absorption) and plot the best-fit model and the fit residuals.

We proceed in fitting the following models to the data (see Tables 3–5) guided by the shape and location of identified absorption and/or emission residuals.

(1) Power law modified by neutral intrinsic absorption at the source. This and all subsequent models include Galactic absorption due to neutral gas (Dickey & Lockman 1990) with a column density of $N_H = 3.94 \times 10^{20} \text{cm}^{-2}$.

(2) Power law modified by neutral intrinsic absorption and a number of absorption and/or emission lines. The Chandra spectra of images (A+B) and C differ significantly due to microlensing (see Section 2.2.1). Guided by the residual features to fits using model 1 (see Figure 1), the Chandra spectrum of image A+B was next fit with a model that included three absorption lines and one emission line and the Chandra spectrum of image C was fit with a model that included three emission lines. The Chandra spectrum of image (A+B) and the XMM-Newton spectrum of (A+B+C+D) differ significantly due to the fact that XMM-Newton does not resolve

![Figure 2. Deconvolved image (0.2–10 keV band) of the 2013 observation of HS 0810+2554. Images A and B are not resolved and image D is not reconstructed, likely due to the low S/N of the Chandra observation. The dashed circles show the regions used for spectral extraction. North is up and east is to the left.](image-url)
the images and due to possible spectral variability between the observations. Guided by the residual features to the fits using model 1 (see Figure 4), the XMM-Newton spectrum was next fit with a model that included two absorption lines and neutral Compton reflection with self-consistent Fe and Ni lines (PEXMON). In model 2, the absorption lines are fit with Gaussians. In the next model, the Gaussian absorption lines are replaced with a more realistic model of outflowing intrinsic ionized absorption.

(3) Power law modified by neutral intrinsic absorption, outflowing intrinsic ionized absorption, and a number of emission lines. Specifically, the Chandra spectrum of image A + B was fit with a model that included one outflowing ionized absorber and one emission line, the Chandra spectrum of image C was fit with a model that included one outflowing ionized absorber and three emission lines, and the XMM-Newton spectrum was fit with a model that included two outflowing ionizing absorbers and neutral Compton reflection with self-consistent Fe and Ni lines (PEXMON).

(4) Power law modified by neutral intrinsic absorption, an outflowing ionized absorber, and scattering by the outflowing wind. This model was fit to the Chandra spectrum of image A+B.

(5) Power law modified by neutral intrinsic absorption, a narrow emission line near the Fe Kα line, an outflowing ionized absorber, and scattering by the outflowing wind. This model was fit to the Chandra spectrum of image A+B.

(6) Power law modified by neutral intrinsic absorption, an outflowing ionized absorber, scattering by the outflowing wind, and neutral Compton reflection from distant parts of the accretion disk. This model was fit to the XMM-Newton spectrum of HS 0810+2554.

(7) Power law modified by neutral intrinsic absorption, an outflowing ionized absorber, scattering by the outflowing wind, and relativistically blurred X-ray reflection from parts of the accretion disk near the black hole. This model was fit to the XMM-Newton spectrum of HS 0810+2554.

Models 4 and 5 are only used to fit the Chandra spectrum of image A+B, which shows a noticeable P-Cygni profile. Models 6 and 7 are only used to fit the XMM-Newton spectrum which shows a noticeable hard-X-ray excess above 15 keV in the rest frame.

For the outflowing ionized absorber with no scattering, we used the XSTAR photoionization model warmabs, and for an outflowing ionized absorber with scattering off the outflowing absorber we used the XSTAR model windabs (Kallman et al. 1996; Kallman & Bautista 2001). For improved accuracy and flexibility, we chose to use the analytic XSTAR versions of the warmabs and windabs models instead of the XSTAR table models.

We model the velocity broadening of the absorption lines by introducing in the XSTAR models' large turbulent velocities. We performed several fits where we allowed the turbulence velocity to vary and found the best-fit values. Because of the

**Notes.** The H-, I-, and V-band data are taken from the CfA-Arizona Space Telescope LEns Survey (CASTLES) of gravitational lenses website http://cfa-www.harvard.edu/glensdata/. Error bars for the X-ray data are at the 68% confidence level.

$^a$ X-ray flux ratios for the 2002 observation.

$^b$ X-ray flux ratios for the 2013 observation.
Figure 4. (a) Observed 46 ks XMM-Newton spectrum of combined A+B+C+D images of HS 0810+2554 fit with Galactic absorption and a power-law model. Note the significant hard X-ray excess. (b) Data shown in panel (a) overplotted with the unfolded best-fit model (model 7 of Table 5) comprised of a photoionization outflow (XSTAR), a direct component (blue curve), and a reflection component (red curve). The direct and reflected components are assumed to be absorbed by the outflowing wind. The arrows indicate the best-fit energies of the absorption lines and the reflection and direct components.

low to moderate S/N of the Chandra and XMM-Newton spectra of HS 0810+2554, the turbulent velocities are not well constrained. For the error analysis of the remaining variables in spectral fits that used the XSTAR model, we therefore froze the turbulent velocities and list these values in Tables 3–5.

For the Compton reflection, we used the PEXMON model (Nandra et al. 2007), which incorporates neutral Compton reflection with self-consistent Fe and Ni lines. For the relativistically blurred X-ray reflection, we used the RELXILL model (García et al. 2014). The results from fitting these models to the Chandra and XMM-Newton spectra of HS 0810+2554 are presented in Tables 3–5.

2.2.1. Spectral Analysis of Chandra Observation of HS 0810+2554

We begin with a description of the fits to the Chandra spectrum of image (A+B) of HS 0810+2554. The intrinsic neutral absorption in image A+B is found to be relatively low with $N_{H} = 0.39^{+0.15}_{-0.13} \times 10^{22}$ cm$^{-2}$ (model 3 of Table 3). In Figure 5, we show the 68%, 90%, and 99% $\chi^2$ confidence contours of the intrinsic hydrogen column density, $N_{H}$ versus the photon index. We consider our constraints on the intrinsic $N_{H}$ from the fits to the Chandra spectrum of A+B to be more reliable than the fits to the spectrum of image C since image C is likely microlensed based on the X-ray flux ratios.

The Chandra spectra of images A+B and C differ significantly, and thus were fit separately. A broad emission line at 6.8$^{+0.2}_{-0.2}$ keV is detected in the spectrum of image A+B and significant absorption lines at energies at 2.2$^{+0.1}_{-0.1}$ keV, 7.8$^{+0.2}_{-0.2}$ keV, and 13.1$^{+1.6}_{-1.5}$ keV (all energies expressed in the rest frame). The inclusion of three Gaussian absorption lines near the absorption features and one Gaussian emission line in model 2 of Table 3 resulted in a significant improvement of the fit compared to the fit using model 1 ($\Delta \chi^2 = 29.8$, $\Delta$ dof = 12, where dof are the degrees of freedom). $\chi^2$ confidence contours of the normalizations of the absorption lines versus their restframe energies based on fits using model 2 of Table 3 are presented in Figure 6. The absorption line at 7.8 keV is detected at >99% confidence, while the lines at 2.2 keV and 13.1 keV are marginally detected at >95% confidence. The energy of the emission line at ~6.8 keV is consistent with Fe XXV and/or Fe XXVI. The presence of this emission line at ~ 6.8 keV and an absorption line at ~7.8 keV is a characteristic feature of a P-Cygni profile supporting the presence of an expanding, outflowing, highly ionized absorber from quasar HS 0810+2554. $\chi^2$ confidence contours of the normalizations of the emission and absorption line of the P-Cygni profile are presented in Figure 7. The P-Cygni lines are detected at >99% confidence. The ratio of the normalizations of the emission to absorption lines of the P-Cygni profile of image A+B is $R_{E} = N_{E}/N_{abs} \sim 0.75$. We note that the ratio measured for the wide-angle outflow of the nearby quasar PDS 456 over five different epochs lies in the range of $R_{E} = 0.19–1.67$ with an average value of $(R_{E}) \sim 0.7$ (Nardini et al. 2015).

We propose as a possible explanation for the difference between the spectrum of the fainter image C and the combined spectrum of images A+B that a microlensing event occurred in image C. This interpretation is consistent with the anomalous X-ray flux ratio of image C (see Table 4). Microlensing may lead to energy shifts of the iron emission lines due to general and relativistic effects as found in the lensed quasar RX J1131–1231 (Chartas et al. 2016). The energies of the best-fit emission lines of image C are presented in Table 3. We note that the emission lines in image C are only detected at the >90% confidence level. We fit the Chandra spectrum of (A+B) with a model that includes an outflowing photoionized absorber and one emission line (model 3 of Table 3). This model can account for the absorption features at around 2.2 keV and 7.8 keV as originating from highly ionized Si and Fe absorbers, respectively.

To model the P-Cygni profile (emission and absorptions lines at ~6.8 keV and ~7.8 keV, respectively) we used the XSTAR model windabs (model 4 of Table 4). The fit with model 4 is acceptable in a statistical sense, however, a residual emission feature remains near the energy of the Fe Kα line. To account for this emission feature, we add a narrow Gaussian line (model 5 of Table 4). A narrow Fe line component is typically detected in the spectra of AGNs along with the relativistically blurred Fe Kα line. The narrow Fe line component is thought to originate in distant, cold matter such as a molecular torus or an optical broad line region (e.g., Krolik et al. 1994; Yaqoob & Padmanabhan 2004; Zhou &

Notes.

$^a$ Model 1 consists of a power law and neutral absorption at the source. Model 2 consists of a power law, neutral absorption at the source, and Gaussian absorption and/or emission lines at the source. Model 2 fit to the XMM-Newton spectrum also includes neutral Compton reflection with self-consistent Fe and Ni lines (PEXMON). All of the model fits include the Galactic absorption toward the source (Dickey & Lockman 1990). Model 3 consists of a power law, neutral absorption at the source and one or two outflowing ionized absorbers at the source, and a number of emission lines. Model 3 fit to the XMM-Newton spectrum also includes neutral Compton reflection with self-consistent Fe and Ni lines (PEXMON). All of the model fits include the Galactic absorption toward the source (Dickey & Lockman 1990).

$^b$ All absorption-line parameters are calculated for the rest frame.

$^c$ Spectral fits were performed using the $\chi^2$ statistic and all errors are for 90% confidence unless mentioned otherwise.

$^d$ $P(\chi^2/\nu)$ is the probability of exceeding $\chi^2$ for $\nu$ degrees of freedom if the model is correct.
Figure 5. The 68%, 90%, and 99% $\chi^2$ confidence contours of intrinsic $N_H$ vs. photon index obtained in the fits to the Chandra spectrum of image A+B and the XMM-Newton spectrum of the combined images. Both spectral fits used model 3 of Table 3.

Figure 6. $\chi^2$ confidence contours between the normalizations of the absorption lines based on fits using model 2 of Table 3 to the Chandra spectrum of image A+B. The 99% confidence contours of $E_{abs}$ are erratic and not closed at the 99% level and are therefore not displayed.

Figure 7. $\chi^2$ confidence contours between the normalizations of the P-Cygni line detected in the Chandra spectrum of image A.

Wang (2005). Another plausible process that could produce the residual emission feature near 6.4 keV is scattering from a low-velocity component of the wind.

In Figure 8, we show the Chandra spectrum of A+B overplotted with the best-fit model (model 5 of Table 4). Figure 8 also shows the unfolded best-fit model that includes the P-Cygni profile, which is a characteristic spectral signature of an outflowing wind. We consider model 5 of Table 4 as our most realistic model which provides a statistically acceptable fit to the Chandra spectrum of image (A+B) of HS 0810+2554. We base any following estimates of the outflow properties for this epoch on the best-fit values of model 5 of Table 4. The $\chi^2$ confidence contours of the covering factor of the wind based on models 4 and 5 of Table 4 are shown in Figure 9. The best-fit values of the covering factor are $f_c = 0.57^{+0.18}_{-0.18}$ (68% confidence) assuming model 4 and $f_c = 0.63^{+0.2}_{-0.13}$ (68% confidence) for model 5.

Model 5 of Table 4 can account for the absorption features at around 2.2 keV and 7.8 keV as originating from highly ionized Si and Fe absorbers, respectively, outflowing with a common velocity of $1.6^{+0.1}_{-0.1}c$. The outflow is highly ionized with an ionization parameter $\zeta$ of $log(\zeta/\text{erg cm s}^{-1}) = 3.15^{+0.13}_{-0.21}$ and a column density of $N_{H,\text{out}} = 2.9^{+0.4}_{-0.2} \times 10^{23} \text{ cm}^{-2}$.

2.2.2. Spectral Analysis of XMM-Newton Observation of HS 0810+2554

We next proceed with the analysis of the XMM-Newton spectrum of images A+B+C+D of HS 0810+2554. Our fit to the XMM-Newton spectrum with a simple power law with Galactic absorption shows residual absorption features and a hard excess above $\sim$15 keV in the rest frame. We fit the spectrum of XMM-Newton of HS 0810+2554 with models 1–3 with the best-fit parameters listed in Table 3. Significant absorption lines are detected at energies of $7.9^{+0.5}_{-0.2} \text{ keV}$ and $10.9^{+0.7}_{-0.6} \text{ keV}$ (all energies expressed in the rest frame). The inclusion of two Gaussian absorption lines near the absorption features in model 2 of Table 3 and neutral Compton reflection with self-consistent Fe and Ni lines resulted in a significant improvement of the fit compared to the fit using model 1 ($\Delta \chi^2 = 44.5$, $\Delta \text{dof} = 9$). The $\chi^2$ confidence contours of the normalizations of the absorption lines versus their rest-frame energies based on fits using model 2 of Table 3 are presented in Figure 10. We continue by fitting the XMM-Newton spectrum of HS 0810+2554 with a model that includes two outflowing photoionized absorbers and reflection (model 3 of Table 3).

Next, we included scattering from the outflow (windabs) to account for a possible weak emission feature near rest frame $\sim$7.5 keV (model 6 of Table 5). We finally considered a model (model 7 of Table 5) that describes the hard excess as...
Table 4

| Model | Parameter | Fitted Values |
|-------|-----------|---------------|
| (A+B) | Γ         | 1.97±0.05     |
|       | N_H       | 0.31±0.09×10^{27} cm^{-2} |
|       | f_e       | 0.58±0.23 (68%) |
|       | N_H,abs   | 2.7±1.0×10^{23} cm^{-2} |
|       | log ζ,abs | 3.14±0.20 erg cm s^{-1} |
|       | v,abs     | 22,000 km s^{-1} |
|       | ζ,abs     | 1.29±0.03 |
|       | χ^2/ν     | 81.3/101 |
|       | P(χ^2/ν)  | 9.25×10^{-1} |

Notes.

a Model 4 consists of a power law, neutral absorption at the source, an outflowing iron absorption at the source, and scattering of the outflowing wind. The model also includes the Galactic absorption toward the source (Dickey & Lockman 1990). Model 5 includes the same components as model 4 with the addition of a narrow emission line near the location of the Fe Kα fluorescent line.

b All absorption-line parameters are calculated for the rest frame.

c Spectral fits were performed using the χ^2 statistic and all errors are for 90% confidence unless noted otherwise.

d P(χ^2/ν) is the probability of exceeding χ^2 for ν degrees of freedom if the model is correct.

relativistically blurred X-ray reflection in place of the neutral Compton reflection considered in model 6. The fit with model 7 implies the presence of two outflowing components with ionization parameters of log(ζ/erg cm s^{-1}) = 3.5±0.3 and log(ζ/erg cm s^{-1}) = 3.2±0.2; column densities of N_H = 3.4±10^{23} cm^{-2} and N_H = 2.9±10^{23} cm^{-2}, and outflow velocities of 0.12±0.06 km s^{-1} and 0.41±0.04 km s^{-1}, respectively. In Figure 11, we show that the fit using model 7 of Table 5 constrains the inclination angle of the accretion disk to be less than 45° (90% confidence).

The main difference between models 6 and 7 is that model 6 assumes distant reflection, whereas model 7 assumes a relativistic, and hence nearby, reflector. Fits to the XMM-Newton spectrum of HS 0810+2554 using models 6 and 7 are acceptable with similar (within the uncertainties) best-fit parameters for the properties of the outflowing absorbers, the reflection fraction, and the inclination angle of the disk (model 7 provides tighter constraints on the inclination angle). We therefore consider models 6 and 7 of Table 5 to be our most realistic models that provide statistically acceptable fits to the XMM-Newton spectrum of image (A+B+C+D) of HS 0810+2554. We base any following estimates of the outflow properties for this epoch on the best-fit values of model 7 of Table 5, however, we note that the results would be similar had we chosen to use the best-fit results from model 6.

We note that the spectral fit to XMM-Newton spectrum requires two ionized absorbers and the fit to the Chandra spectrum only one. As indicated in Figure 6, the absorption line at ~13 keV is only marginally detected in the Chandra spectrum and no useful constraints can be obtained by including a second ionized absorber to model this line in the Chandra spectrum. XMM-Newton is more efficient than Chandra at higher energies, which may explain why the second high-energy absorption line is detected at a higher confidence level in the XMM-Newton spectrum.

2.3. A Group of Galaxies Near HS 0810+2554

In Figure 12, we show the 100 ks Chandra image of HS 0810+2554 and a nearby group of galaxies that contributes to the lensing of this quasar. The image was binned with a bin size of 0.1 arcsec and adaptively smoothed with the CSMOOTH tool developed by Ebeling et al. (2006). The 100 ks Chandra observation compared to the previous 5 ks one provides better constraints of the mass profile and the temperature of this galaxy group. These mass estimates were used to evaluate the convergence parameter κ(x),

$$κ(x) = \frac{\Sigma(x)}{\Sigma_{cr}},$$

where Σ(x) is the surface mass density of the galaxy group as a function of the cylindrical radius x (e.g., Chartas et al. 1998) and Σ_{cr} is the critical surface mass density (see, e.g., Schneider et al. 1992). The distortion of the source produced by convergence is isotropic. An external perturber will also produce distortion, referred to as shear (γ), that stretches the intrinsic shape of the source in a preferred direction. The shear from the galaxy group can be expressed as

$$γ = \beta_\text{el} = \frac{r_c}{d_s},$$

where β_{el} = r_c/d_s, r_c is the galaxy group core radius and d_s is the distance from the group center to the center of HS 0810+2554 (see Kochanek 1991).

The spatial and spectral analysis of the galaxy group follows steps similar to those presented in Chartas et al. (2014). Our revised fit to the X-ray brightness profile of the galaxy group using a β model indicates best-fit values for its ellipticity of e = 0.08±0.04, β = 0.38±0.01, and for the core radius of the group of r_0 = 0.024±0.005 (0.37 kpc). We extract the Chandra and XMM-Newton spectra of the galaxy group from a 50 arcsec radius circle centered on the X-ray group center. The spectra were jointly fit with a model consisting of emission from hot, diffuse gas based on the XSPEC model mekal (Mewe et al. 1985; Kaaret 1992; Liedahl et al. 1995), modified by Galactic absorption. We obtain best-fit values for the redshift, temperature, and metal abundances of z = 0.082±0.009, T_e = 0.81±0.02 keV, and A = 0.53±0.08 solar, respectively (all errors are at the 90% confidence level). The Chandra and XMM-Newton spectra of the galaxy group overplotted with our best-fit model are shown in Figure 13. The convergence and external shear due to the group at the lens position based on our analysis of the 100 ks Chandra observation are found to be κ ≈ 0.026±0.003.
2.4. Extended Radio Emission Near HS 0810+2554

VLA observations of the gravitationally lensed quasars HS 0810+2554, RX J0911+0511, HE 0435–1223, and SDSS J0924+0219 have revealed radio emission in these radio-quiet objects (Jackson et al. 2015). Of particular interest is the VLA image of HS 0810+2554, which shows a faint arc around images A and B which is likely formed by extended emission near the quasar and lensed by the intervening galaxy. Jackson et al. model this arc and infer an extended radio source size of about 10 mas that corresponds to a physical size of about 90 pc. This is close to the predicted size of the inner portion of the narrow-line region (NLR) for an AGN with the luminosity of HS 0810+2554.

To test whether the ultrafast outflow is energetic enough to produce the observed radio emission of HS 0810+2554, we compare the unlensed radio luminosity of HS 0810+2554 at 1.4 GHz with the kinetic luminosity of the wind. We find the luminosity at 1.4 GHz to be \( \nu L_\nu \sim 1 \times 10^{39} \text{ erg s}^{-1} \) and the kinetic luminosity of the outflow to lie in the range \( 5 \times 10^{46} \text{ erg s}^{-1} \). If the radio synchrotron emission of HS 0810+2554 is produced during the acceleration of particles of the AGN outflow as it collides with the surrounding medium, then we find that the efficiency of conversion is significantly less than that of supernova-driven winds.

Zakamska et al. (2014) find from the analysis of a sample of obscured radio-quiet quasars that their radio luminosities are correlated with the velocity of outflowing narrow-line gas. They suggest that the weak radio emission of radio-quiet quasars may be produced by particles accelerated in the shocks within the quasar-driven outflows. Comparing with Figure 10 of Zakamska et al., which plots the radio luminosities of a sample of radio-quiet AGNs versus the velocity width of the [O iii] emission, we find that the radio luminosity of HS 0810+2554 falls on the borderline between the radio luminosities of Seyfert galaxies and radio-quiet quasars.

Figure 8. (a) Observed 100 ks Chandra spectrum of combined images A+B of HS 0810+2554 fit with model 5 of Table 4 which includes a P-Cygni component. (b) The unfolded best-fit model to the fit shown in panel (a). The vertical dashed lines indicate the observed-frame energies of the Si XIV, S XVI, and Fe XXV resonance spectral lines. The inferred common outflow velocity of the absorber is \( v = 0.1c \).

Figure 9. \( \chi^2 \) confidence contours of the covering factor of the wind for models 4 and 5 of Table 4. The best-fit values of the covering factor are \( f_c = 0.57^{+0.18}_{-0.18} \) (68%) assuming model 4 and \( f_c = 0.6^{+0.19}_{-0.18} \) (68%) for model 5.

Figure 10. \( \chi^2 \) confidence contours between the normalizations of the absorption lines and their rest-frame energies based on fits using model 2 of Table 3 to the XMM-Newton spectrum of image A+B+C+D.

3. DISCUSSION

The 100 ks Chandra and 46 ks XMM-Newton observations of the NAL quasar HS 0810+2554 confirm the presence of a highly ionized and relativistic outflow in this quasar and
include the Galactic absorption toward the source, the accretion disk component in the rest-frame energy band of 20 keV, ionized absorbers at the source, scattering of the low-velocity outflowing ionized absorbers at the source, consistent Fe and Ni lines consisting of a power law, neutral absorption at the source, two outflowing components in the rest-frame energy band of 20 keV.

**Notes.**
- Model 6 consists of a power law, neutral absorption at the source, two outflowing ionized absorbers at the source, scattering of the low velocity outflowing component (abs1), and neutral Compton reflection with self-consistent Fe and Ni lines (PEXMON). The normalizations of the direct (reflection) component is the photon flux at 1 keV (photons keV$^{-1}$ cm$^{-2}$ s$^{-1}$) of the power law (reflection) component only and in the Earth frame. Model 6 consists of a power law, neutral absorption at the source, two outflowing ionized absorbers at the source, scattering of the low velocity outflowing component (abs1), and relativistic reflection off an ionized disk. Parameters of model 6 include the spin of the black hole (a), and the inner and outer radii of the accretion disk $r_{in}$ and $r_{out}$, respectively. For models 6 and 7, $R_{break}$ is defined as the ratio of the flux reflected by the disk to the flux of the direct power-law component in the rest-frame energy band of 20–40 keV. Parameters listed as fixed are held fixed to the listed value during the fit. All of the model fits include the Galactic absorption toward the source (Dickey & Lockman 1990).
- All absorption-line parameters are calculated for the rest frame.
- Spectral fits were performed using the $\chi^2$ statistic and all errors are for 90% confidence unless mentioned otherwise.
- $P(\chi^2/\nu)$ is the probability of exceeding $\chi^2$ for $\nu$ degrees of freedom if the model is correct.

**Table 5**
Results from Fits to the XMM-Newton Spectrum of HS 0810+2554 with a Model That Includes Reflection and a P-Cygni Profile

**Figure 11.** Fits to the XMM-Newton spectrum of HS 0810+2554 constrain the inclination angle of the accretion disk (model 7 of Table 5). The $\chi^2$ confidence plot indicates an inclination angle of $<45^\circ$ (90% confidence), which is consistent with models that posit NALQSOs as objects observed at relative low inclination angles.

**Figure 12.** Adaptively smoothed image of the 100 ks Chandra observation of HS 0810+2554. Our spectral analysis confirms our previous result, which was based on a 5 ks exposure (Chartas et al. 2014), that the extended emission 58° west of HS 0810+2554 is produced by a galaxy group at $z \approx 0.08$.

provide tight constraints on the properties of the wind. These improved constraints allow for more accurate estimates of the mass-outflow rate and the rate of kinetic energy injection than those provided by the previous 5 ks Chandra observation.

Our analysis of the P-Cygni profile detected in the Chandra spectrum of image (A+B) constrains the covering factor of the wind to be $f_c = 0.6^{+0.2}_{-0.3}$. As we discuss later in this section, this value is likely a lower limit and it is subject to a few caveats. This large covering factor is consistent with studies of NAL quasars (e.g., Misawa et al. 2007; Culliton et al. 2012; Simon et al. 2012) that indicate the true fraction of quasars with a quasar-driven outflow responsible for producing NALs to be $>40\%$. We are assuming that the UV and X-ray observations are sampling different parts of the outflow with the X-ray absorbers located closer to the continuum source, thus having a higher ionization level than the UV absorbers, which are likely located further out. The detection of a Si xiv resonance absorption line in HS 0810+2554 blueshifted by the same
The Astrophysical Journal, 824:53 (14pp), 2016 June 10

Figure 13. Chandra and XMM-Newton X-ray spectra of the galaxy group centered 58° west of HS 0810+2554 along with the best-fit thermal mekal model (joint fit). The model is consistent with a plasma temperature of $T_{\text{e}} \sim 0.8$ keV, abundance of $A \sim 0.53$ solar, and a redshift of $z \sim 0.08$. Residuals are in units of standard deviations with error bars of size 1σ.

To estimate the bolometric luminosity of HS 0810+2554, we correct for the lensing magnification and apply a bolometric correction to the 2–10 keV luminosities based on the empirical relations presented in Lusso et al. (2012). The lensing magnification was determined by modeling the gravitational lens system HS 0810+2554 using the gravitational lens adaptive-mesh fitting code glafic version 1.1.6 (Oguri 2010). The lens was modeled as a singular isothermal ellipsoid plus an external shear from the nearby galaxy group. We incorporate the more accurate values of $\kappa$ and $\gamma$ obtained from the 100 ks observation in our lens model to better constrain the image magnifications, the unlensed luminosity of HS 0810+2554, and the image time delays. We find that the magnifications of the images are $\mu_A \sim 42$, $\mu_B \sim 43$, $\mu_C \sim 11$, and $\mu_D \sim 7$. The time delays between images are found to be $t_{\text{delay}} = 86$ s, $t_{\text{delay}} = 6.740$ s, $t_{\text{delay}} = 6.653$ s, and $t_{\text{delay}} = 25.833$ s. The mean Eddington ratio for an AGN with the black hole mass and redshift of HS 0810+2554 is $\lambda_{\text{Edd}} \sim 0.1$. Lusso et al. (2012) indicate that the 2–10 keV bolometric correction for a type I AGN with an Eddington ratio of $\lambda_{\text{Edd}} \sim 0.1$ is $\lambda_{\text{2,10keV}} \sim 30$. The bolometric luminosity of HS 0810+2554 during the 100 ks Chandra observation is $L_{\text{bol}} = 1.1(85/\mu_{AB})\lambda_{\text{2,10keV}}/30 \times 10^{45}$ erg s$^{-1}$, where the lensing magnification of image (A+B) is $\mu_{AB} = 85$ and the bolometric correction is $\lambda_{\text{2,10keV}} = 30$ for an unlensed 2–10 keV luminosity of $3.73 \times 10^{43}$ erg s$^{-1}$. The bolometric luminosity of HS 0810+2554 during the 46 ks XMM-Newton observation is $L_{\text{bol}} = 1.4 \times 10^{45}$ erg s$^{-1}$.

We note that the bolometric luminosity of HS 0810+2554 is not well constrained because of the large uncertainty in the 2–10 keV bolometric correction. An independent estimate of $L_{\text{bol}}$ is provided from the monochromatic luminosities of HS 0810+2554 at 1450 Å and 5100 Å based on the empirical relations of Runnoe et al. (2012). Assaf et al. (2011) list the continuum monochromatic luminosities $\log(\lambda L/\text{erg s}^{-1})$ of HS 0810+2554 at 1450 Å and 5100 Å to be 44.44 and 44.84, respectively. Using the recommended bolometric corrections of Runnoe et al., we estimate the bolometric luminosities based on the 1450 Å and 5100 Å continuum monochromatic luminosities of HS 0810+2554 to be $1.1 \times 10^{43}$ erg s$^{-1}$ and $3.7 \times 10^{43}$ erg s$^{-1}$, respectively. For the purpose of estimating the efficiency of the outflow, we adopt a mean value for the bolometric luminosity of $L_{\text{bol}} = 1.8 \pm 1.3 \times 10^{45}$ erg s$^{-1}$, which is based on the X-ray, UV, and optical bolometric corrections. We assumed a global covering factor for the outflowing absorber of $\epsilon_c = 0.6_{-0.3}^{+0.2}$ based on our fits to the P-Cygni profile observed in the Chandra spectrum of HS 0810+2554.

To estimate the mass-outflow rate and outflow efficiency, we assumed a fraction $r/\Delta r$ ranging from 1 to 10 based on theoretical models of quasar outflows (e.g., Proga et al. 2000). Assuming that the maximum outflow velocity is produced by gas that has reached its terminal velocity, one obtains the estimated error bars. Specifically, the two outflow components detected in the Chandra observation have $v_{\text{abs,1}} = 0.10_{-0.01}^{+0.01}$ and $v_{\text{abs,2}} = 0.50_{-0.08}^{+0.14}$ (component 2 is only marginally detected in model 2) and the two outflow components detected in the XMM-Newton observation have $v_{\text{abs,1}} = 0.12_{-0.01}^{+0.02}$ and $v_{\text{abs,2}} = 0.41_{-0.04}^{+0.07}$. The significance of the detections of the absorption lines in the Chandra and XMM-Newton observations are shown in the confidence contour plots of Figures 6 and 10, respectively.

In Table 6, we list the 0.2–2 keV and 2–10 keV fluxes and luminosities from the combined images of HS 0810+2554 since the images are not resolved with XMM-Newton. We find significant flux variability. Specifically, the 0.2–2 keV flux increased from $4.0_{-0.3}^{+0.1} \times 10^{-13}$ erg s$^{-1}$ cm$^{-2}$ to $6.4_{-0.3}^{+0.3} \times 10^{-13}$ erg s$^{-1}$ cm$^{-2}$ between the 2013 December and 2014 October observations. The increase in the 0.2–2 keV flux is accompanied by a significant decrease of the intrinsic neutral column density, the significant change in the neutral intrinsic column density, the velocity of the outflow does not appear to have changed. We conclude that the soft X-ray flux variability is possibly caused by a change in the intrinsic neutral column density.

To estimate the mass-outflow rate of the wind, we assume a spherically symmetric wind with a covering factor of $f_c$ (e.g., Lamers & Cassinelli 1999, implemented in XSPEC as the windabs model, whose assumptions we describe below). We approximate $N_H \sim n(r)\Delta r$, where $n(r)$ is the number density of the gas. We use the following expressions to estimate the mass-outflow rate and the efficiency of the outflow:

\[
\dot{M}_i = 4\pi r_i (\Delta r_i) N_{H,i} m_p v_{\text{wind},i} f_{c,i}
\]

\[
\epsilon_{k,i} = \frac{\dot{M}_i v_{\text{wind},i}^2}{2 L_{\text{bol}}},
\]

where $\Delta r_i$ is the thickness of the absorber at radius $r_i$, $N_{H,i}$ is the hydrogen column density, $v_{\text{wind},i}$ is the outflow velocity of the X-ray absorber, $f_{c,i}$ is the global covering factor of the absorber, $i$ indicates the absorbing component, and $L_{\text{bol}}$ is the bolometric photon luminosity of the quasar.

Estimates of the properties of absorbing outflows in HS 0810+2554 for components detected at >99% confidence are presented in Table 7. We base our outflow estimates for the Chandra and XMM-Newton epochs on the best-fit results of model 5 (Table 4) and model 7 (Table 5), respectively.

The outflow velocities in the Chandra and XMM-Newton observations of HS 0810+2554 are similar if one considers the amount as that of the Fe xxv resonance absorption line supports the presence of a relativistic outflow (see Figures 6 and 8).
approximation $R_{\text{launch}} \sim a$ a few times $R_c (c/v_{\text{wind}})^2$, where $v_{\text{wind}}$ is the observed outflow velocity, $R_{\text{launch}}$ is the launch radius of the outflow, and $R_c = 2GM/c^2$. Based on our estimated maximum outflow velocity ($v \sim 0.4c$), we expect $r$ to be similar to $R_{\text{launch}}$ and to range between $3 R_c$ and $20 R_c$. Our assumed range of $r$ is conservative, ranging from the innermost stable circular orbit (ISCO) radius to $20 R_c$. Launching a wind at significantly smaller radii than the ISCO radius is unlikely since general relativistic (GR) effects on an absorber launched within the ISCO radius would result in significant redshifts of the absorption lines and launching radii greater than $20 R_c$ will result in even larger values of the mass-outflow rate assuming that the mass-outflow rate is given by the expression presented in Equation (1). We note, however, that in Equation (1), we approximate $N_{\text{H}} \sim n(r)\Delta r$, which assume a continuous wind smoothly distributed over the disk, and do not consider the velocity gradients of the wind or include special relativistic corrections (see Equation (4) of Saenz & Chartas 2011).

We used a Monte Carlo approach to estimate the errors of $M_i$ and $\epsilon_k$. The values of $v_{\text{wind}}$ and $N_{\text{Habs}}$ were assumed to have normal distributions within their error limits. The values of $f_c$, $r/\Delta r$, and $r$ were assumed to have uniform distributions within their error limits. By multiplying these distributions and with the appropriate constants from Equations (1) and (2), we obtained the distributions of $M_i$ and $\epsilon_k$. We finally determined the mean values of the distributions of $M_i$ and $\epsilon_k$ and estimated the 68% confidence ranges.

In Table 7, we list the total hydrogen column densities $N_{\text{H}}$ of the X-ray absorption lines, the outflow velocity of each absorption component, the mass-outflow rates, and the efficiency of the outflows. The large fraction of kinetic to electromagnetic luminosity implies that radiation driving alone cannot explain the acceleration of this highly ionized absorber. Magnetic driving likely provides a significant contribution to the acceleration of the X-ray wind (e.g., Kazanas et al. 2012; Fukumura et al. 2014). The mass-outflow rate of HS 0810+2554 is found to lie in the range $1.5-3.4 M_\odot \text{yr}^{-1}$, which is comparable to the accretion rate of HS 0810+2554 which we estimate to be $1.8 \times 10^{-3} (L_{2554}/\eta) M_\odot \text{yr}^{-1} \sim 1 M_\odot \text{yr}^{-1}$, where we assumed a typical accretion efficiency of $\eta = 0.1$. To calculate the mass-outflow rate, we have assumed a continuous biconical outflow with a covering factor. Another possibility is that the wind is not continuous but made up of clouds. We note that Equation (1) is approximately valid in the case of clouds too, as long as the clouds are distributed throughout the shell of thickness $\Delta r$. Future observations with the X-ray satellite ATHENA, with its high-energy resolution, may be able to show whether the blueshifted broad X-ray absorption features are caused by a velocity gradient in a continuous wind. The confirmation of smooth, broad absorption lines would suggest that the outflow is made of a continuous stream of ionized material instead of an outflow of dense clouds.

The XMM-Newton spectrum of HS 0810+2554 shows evidence of absorption and reflection (see Figure 4). Model 6 assumes a distant reflector and two outflowing absorbers, whereas model 7 includes a nearby reflector and two outflowing absorbers. In both cases, the reflection component lies below the direct component, except for the rest-frame energy range of 15–50 keV. If we define the reflection fraction, $R$, as the ratio of the flux reflected by the disk to the flux of the direct power-law component in the rest-frame energy band of 20–40 keV, then we find that $R = 1.4 \pm 0.6$ (for model 7 of Table 5). If the light bending of the direct component is not important, then the direct component should generally be larger than the reflected one. However, several recent observations and simulations indicate that the reflection component can dominate in some AGNs and the relative strength of the reflected versus direct X-ray emission increases with the spin of the black hole. In particular, recent studies of AGNs have attempted to disentangle the direct emission from the reflected X-ray emission (e.g., Fabian et al. 2014; Gallo et al. 2015; Keck et al. 2015; Zoghbi et al. 2015). To complicate the
analysis further, the reflected X-ray emission of AGNs is thought to be comprised of two main components: 
(a) backscattering from distant, cold material in a dusty molecular torus or in the broad line region gas, and 
(b) backscattering from ionized disk material near the black hole. The reflected emission from the inner disk is expected to be blurred due to relativistic effects. The reflection fraction in some cases is found to be larger than 1 (e.g., Gallo et al. 2015; Keck et al. 2015; Zoghbi et al. 2015). Reflection-dominated X-ray spectra can be caused by light bending of a portion of the direct emission component from the hot corona into the black hole resulting in an increase in the reflection fraction. Dauer et al. (2014) show through simulations that reflection fractions in excess of 2 are only possible for rapidly spinning black holes.

There are additional effects that may distort the X-ray emission from the corona such as scattering off an outflowing wind and absorption by material near the black hole (e.g., Miller et al. 2009; Sim et al. 2012). The spectral contribution from scattering off outflowing X-ray absorbers has been simulated in Sim et al. (2012). In their simulations (see Figures 6 and 7 of Sim et al. 2012), the scattering off the wind mostly affects the spectral region near the Fe Kα line (6.4–7 keV) but does not produce an excess at higher rest-frame energies (10–100 keV) similar to that produced by backscattering from the optically thick accretion disk. The Sim et al. simulations also indicate the contribution from scattering to be inclination-angle dependent. Specifically, the spectral distortion caused by scattering off of the wind near the iron line region decreases with decreasing inclination angle. We therefore conclude that the hard excess observed above rest-frame energies of ~12 keV in the XMM-Newton spectrum of HS 0810+2554 is not the result of scattering off the outflowing X-ray absorber, but is likely the result of backscattering from the accretion disk.

There are several assumptions that are made in the windabs model that we used to fit the P-Cygni profile of the spectrum of image A+B. The windabs model assumes a spherical and isotropic outflow ionized by a compact central continuum source and with a covering factor $f_c$. In the case of HS 0810+2554, the central ionizing source of the outflowing X-ray absorbing material is the hot corona. Microlensing studies of radio-quiet quasars with black hole masses ranging between $10^4 M_\odot$ and $10^5 M_\odot$ indicate that their hot coronae are compact with sizes close to 6$r_g$ (Chartas et al. 2016). We therefore consider as a reasonable assumption that the fastest wind of HS 0810+2554 is being illuminated by a compact central continuum source. The kinetic and geometric structure of ultrafast winds in radio-quiet quasars is not well known. A departure of the outflow from isotropy will generally distort the shape of the reflected component (emission line) of the P-Cygni profile. The windabs model does not account for the presence of the accretion disk, which may shield a significant portion of the reflected resonant emission from the wind. Dorodnitsyn (2009) has simulated the effect of shielding of an outflow by the AGN accretion disk and finds that for small inclination angles, shielding results in significant attenuation of the red wing of the emission line of the P-Cygni profile (see Figure 12 of Dorodnitsyn 2009). This suggests that the value of the covering factor obtained in our analysis using windabs is likely an underestimate, and thus provides a lower limit of the true covering factor. We reproduced this effect by simulating a spectrum with a P-Cygni profile with an emission line of twice the observed strength (unblocked case) and fit the spectrum using the windabs model. The covering factor in this case increased by a factor of 2. We conclude that the covering factor of the wind in HS 0810+2554 is likely large with $f_c \gtrsim 0.6$. Future observations with the high-energy resolution calorimeter on board the X-ray satellite ATHENA should be able to resolve the structure of the P-Cygni profile and provide constraints on disk shielding and the presence of GR effects on the absorption profile.

The fits to the XMM-Newton spectrum of HS 0810+2554 using models 6 and 7, which include a P-Cygni profile, do not place any useful constraints on the opening angle of the wind. Scattering from the outflowing X-ray absorber is expected to produce an emission line near the energy of the Fe Kα line, but it is not detected at a high significance level in the XMM-Newton spectrum as it is in the Chandra spectrum of image (A+B). This could in part be caused by the fact that the XMM-Newton spectrum combines all images and the P-Cygni profile may be smeared if the spectra of images A+B and C differed during the observation. Another possible reason is the variability of the covering fraction. There are hints of such variability of the covering fraction in the ultrafast outflow of PDS 456 (see Figure 1 and Table S2 in Nardini et al. 2015).

We have not investigated more complex spectral models that include multiple reflectors and scatterers due to the relatively low S/N of the available X-ray spectra of HS 0810+2554 and the lack of spectral coverage in a higher energy range where the Compton reflection component is expected to peak. A scheduled joint observation of HS 0810+2554 with Chandra and NuSTAR will provide improved constraints of the kinematic and ionization properties of the ultrafast outflow and reflector/s of HS 0810+2554 by fitting outflow/reflection models to the 0.3–80 keV spectrum of HS 0810+2554.

4. SUMMARY

The 100 ks Chandra and 46 ks XMM-Newton observations of the gravitationally lensed $z = 1.51$ NAL quasar HS 0810+2554 indicate (at >99% confidence) the presence of a highly ionized and relativistic outflow in this highly magnified object. These observations confirm our marginal detection of an ultrafast wind in this object based on an earlier 5 ks Chandra observation.

We summarize the main results from the latest X-ray observations of HS 0810+2554 as follows.

1. A highly ionized and relativistic wind is present in both the 100 ks Chandra and 46 ks XMM-Newton observations of HS 0810+2554. We find the ionization parameter of the X-ray outflowing absorber to lie in the range log ($\xi/\text{erg cm s}^{-1}$) = 3.2–3.3, the hydrogen column density to lie within the range $N_{\text{Habs}} = 2.9–3.4 \times 10^{23} \text{cm}^{-2}$, and the outflow velocity components to lie within the range $v_{\text{abs}} = 0.1–0.41 \text{c}$.

2. Our interpretation of the relativistic nature of the outflow is consistent with the detection of an Si xiv absorption line blueshifted by the same amount as the highly ionized Fe line in the 100 ks Chandra spectrum of image A+B. The presence of an outflow is also supported by the detection of a P-Cygni profile in the 100 ks Chandra spectrum of image A+B. We constrain the covering factor $f_c$ of the relativistic wind by fitting the P-Cygni profile. We find $f_c = 0.6_{-0.3}^{+0.2}$, indicating that the wind is wide-angled and
therefore important in the feedback process because it provides efficient coupling of the outflow to the surrounding intergalactic medium. The value of the covering factor obtained in our analysis using windabs is likely an underestimate because of the shielding of the outflow by the accretion disk, and thus provides a lower limit to the true covering factor. We conclude that the covering factor of the wind in HS 0810+2554 is likely large with $f_c \gtrsim 0.6$, assuming disk shielding.

3. A hard X-ray excess component is detected in the 46 ks XMM-Newton spectrum of HS 0810+2554. A possible explanation is reflection from nearby or distant regions of the accretion disk. By modeling the hard X-ray excess as blurred relativistic reflection from the accretion disk, we constrain the inclination angle of the disk to be $\lesssim 45^\circ$ (90% confidence). We note that this result is model dependent (see Table 5) and that due to the relatively low S/N of the available spectra of HS 0810+2554 several parameters of model 7 (see Table 5) were fixed during the spectral fit. A scheduled joint Chandra and NuSTAR observation of HS 0810+2554 will provide tighter constraints on the properties of the reflector. Such a small inclination angle, if confirmed with follow-up observations, is consistent with models that posit NAL quasars as objects observed at relatively low inclination angles.

4. The mass-outflow rate of HS 0810+2554 is found to lie in the range $M = 1.5-3.4 \times 10^{33} \text{ yr}^{-1}$ and is comparable to the accretion rate $1 M_\odot \text{ yr}^{-1}$ (assuming an accretion efficiency of 0.1 and an Eddington ratio of 0.1). The large fraction of kinetic to electromagnetic luminosity of $(\epsilon_k = 9 \pm 3)$ implies that radiation driving alone cannot explain the acceleration of this highly ionized absorber. Magnetic driving likely provides a significant contribution to the acceleration of the X-ray wind.

5. The deeper X-ray observations provide tighter constraints on the properties of a nearby group of galaxies that contributes to the gravitational lensing of HS 0810+2554. In particular, joint fits to the Chandra and XMM-Newton spectra of the group indicate a plasma temperature of $T_e \approx 0.8 \text{ keV}$, an abundance of $A \sim 0.53 \text{ solar}$, and a redshift of $z \approx 0.08$. We used these new constraints to improve our lens model of HS 0810+2554. We find that the total magnification of the background quasar is $\mu_{ABCD} \sim 103$.

6. The Chandra spectra of images C and A+B differ significantly. We propose as a possible explanation for the difference between these spectra a microlensing event occurring in image C. This interpretation is consistent with the anomalous X-ray flux ratio of image C (see Table 4). Microlensing may lead to energy shifts of the iron emission lines due to general and relativistic effects as found in the lensed quasar RX J1131–1231 (Chartas et al. 2016).
