Abstract: Land surface soil moisture (SM) plays a critical role in hydrological processes and terrestrial ecosystems in areas affected by desertification. Passive microwave remote sensing products such as the Soil Moisture Active Passive (SMAP) have been shown to monitor surface soil water well. However, the coarse spatial resolution and lack of full coverage of these products greatly limit their application in areas undergoing desertification. In order to overcome these limitations, a combination of multiple machine learning methods, including multiple linear regression (MLR), support vector regression (SVR), artificial neural networks (ANN), random forest (RF) and extreme gradient boosting (XGB), have been applied to downscale the 36 km SMAP SM products and produce higher spatial-resolution SM data based on related surface variables, such as vegetation index and surface temperature. Areas affected by desertification in Northern China, which are very sensitive to SM, were selected as the study area, and the downscaled SM with a resolution of 1 km on a daily scale from 2015 to 2020 was produced. The results show a good performance compared with in situ observed SM data, with an average unbiased root mean square error value of 0.049 m$^3$/m$^3$. In addition, their time series are also consistent with precipitation and perform better than some common gridded SM products. The data can be used to assess soil drought and provide a reference for reversing desertification in the study area. This dataset is freely available at https://doi.org/10.6084/M9.FIGSHARE.16430478.V5 (Rao et al., 2021).

Keywords: Soil moisture; SMAP; Multiple machine learning; Surface variables; Desertification.

1. Introduction

Surface soil moisture (SM) plays a very important role in water-energy cycle processes (Sandholt et al., 2002; De Santis et al., 2021) and is an important source of water for plants and soil microbes (Wang et al., 2007; Gu et al., 2008; Mallick et al., 2009). Large-scale areas of northern China are undergoing desertification because of scarce precipitation and insufficient SM. The accurate acquisition of SM is valuable to ecological conservation and revegetation in arid areas of Northern China.

In the past, SM data were mainly obtained through ground measurements or the assimilation of products based on land surface models such as the Global Land Data Assimilation System (GLDAS). Although most accurate SM data at different
soil depths can be obtained, field measurements and in situ observations are limited due to the high cost and labor intensity involved in their collection and are generally not representative of soil water status over larger areas (Rahimzadeh-Bajigiran et al., 2013; Zhao et al., 2018; Bai et al., 2019). With the development of remote sensing technologies, continuous SM estimates can be generated at regional and global scales (Peng et al., 2021). Compared to ground measurements, remote sensing products can provide good spatial and temporal coverage of SM with a relatively low cost to the user (Zeng et al., 2015; Zhao et al., 2018; Meng et al., 2020). Data assimilation products largely depend on the accuracy of the land surface model and the original data (Zawadzki and Kędzior, 2016). They generally have low accuracy in areas where ground measurements are scarce, which is a problem that can be overcome with remote sensing.

At present, there are many remotely sensed SM data, some of which are from microwave remote sensing satellites, including active and passive types. SM retrievals from active sensors like Synthetic Aperture Radar (SAR) are sensitive to scattering and greatly affected by the surface roughness and vegetation types (Lievens et al., 2011; Wagner et al., 2013). Unlike active sensors, passive microwave radiometers or sensors have almost no scattering and generate very stable SM products (Abbaszadeh et al., 2019). Common passive microwave SM products are listed in Table 1 below. Some studies have compared these products and found that SMAP SM products have higher accuracy and robustness than other remotely sensed SM products (Liu et al., 2019; Wang et al., 2021).

**Table 1: Information of five common passive microwave soil moisture (SM) products.**

| SM Datasets (Abbreviation) | Name | Production source | Resolution | Temporal Coverage | Equator Crossing Time |
|---------------------------|------|-------------------|------------|-------------------|----------------------|
| AMSR-E/Aqua Daily L3      | Advanced Microwave Scanning Radiometer-Earth Observing System | National Aeronautics and Space Administration (NASA) National Snow and Ice Data Center Distributed Active Archive Center (NSIDC) | 25 km; Daily | 2002-2011 | 1:30 PM Ascending 1:30 AM Descending |
| SMOS                      | Soil Moisture and Ocean Salinity | European Space Agency (ESA) | 25 km; Daily | 2010-present | 6:00 PM Ascending 6:00 AM Descending |
| FY3B                      | Fengyun-3B | National Satellite Meteorological Center | 25 km; Daily | 2011-present | 1:40 PM Ascending 1:40 AM Descending |
| GCOM-W1/AMSR2             | Advanced Microwave Scanning Radiometer 2 | Japan Aerospace Exploration Agency (JAXA) | 0.25°/0.1°; Daily | 2012-present | 1:30 PM Ascending 1:30 AM Descending |
| SMAP                      | Soil Moisture Active Passive | National Aeronautics and Space Administration (NASA) | 36 km; Daily | 2015-present | 6:00 AM Ascending |

Passive microwave SM products have been applied at watershed and national scale (Fang and Lakshmi, 2014; Meng et al., 2020). However, due to their coarse spatial resolution, microwave SM products have limited applicability to small-scale areas. Compared to microwave sensors, optical satellites such as MODIS and Landsat have a finer spatial resolution. Some observations generated from optical satellites provide good information about SM, such as vegetation index (VI) and land
surface temperature (LST) (Wang et al., 2007; Sun et al., 2012). Many experiments have tried to use these two parameters from optical remote sensing to retrieve surface SM (Mallick et al., 2009; Fang et al., 2013). Based on the LST and VI triangle space, Sandholt et al. (2002) proposed the temperature vegetation dryness index (TVDI) and used it to assess the SM status. Despite their higher resolution, however, optical remote sensing data do not allow to directly retrieve true SM.

Some studies have tried to use surface variables from optical observations to improve the spatial resolution of passive remotely sensed SM products (Peng et al., 2017). Zhao et al. (2017) used the triangle method and Landsat satellite observations to disaggregate coarse-resolution SM data. Some studies have also shown that polynomial regression is effective in SM and optical observations (Zhao and Li, 2013; Piles et al., 2016). However, these methods have some shortcomings in representing the nonlinear relationship between SM and other surface variables (Zhao et al., 2018; Hu et al., 2020). Machine learning methods can be applied to show the nonlinear relationships between SM and surface variables. Random forest (RF) and artificial neural network (ANN) have been widely used in previous studies due to their high generalization ability and robustness (Yao et al., 2017; Liu et al., 2020; Demarchi et al., 2020; Chen et al., 2021). Chen et al. (2021) developed the global surface SM dataset covering 2003–2018 at 0.1° resolution with neural networks and some related variables. Im et al. (2016) used machine learning approaches (RF, boosted regression trees, and Cubist) to downscale AMSR-E SM data in South Korea and Australia and found RF to be superior to the other downscaling methods. Although these machine learning methods perform well in constructing nonlinear regression models, there are still some shortcomings. For example, neural networks are prone to overfitting when there are inefficient samples (Piotrowski and Napiorkowski, 2013) or variables that are weakly correlated with the dependent variable (Elshorbagy and Parasuraman, 2008; Ågren et al., 2021). Extreme gradient boosting (XGB), as a new ensemble learning method (Chen and Guestrin, 2016), performs well in some fields (Wang et al., 2020; Fan et al., 2021; Ma et al., 2021), but it has rarely been used for soil moisture downscaling.

The selection of feature variables is critical for regression models. In addition to LST and VI mentioned above, variables such as terrain and soil conditions also have a significant impact on SM. Abbaszadeh et al. (2019) downscaled SMAP radiometer SM products over the continental United States using MODIS products (including NDVI and LST), precipitation and topographic data, and also evaluated the influence of soil texture on SM. Zhao et al. (2018) added additional surface variables, such as LST leaf area index (LAI), normalized difference water index (NDWI), surface albedo and the solar zenith angle. Hu et al. (2020) added the normalized shortwave-infrared difference bare soil moisture index (NSDSI), horizontally polarized Brightness Temperature (TBh) and vertically polarized Brightness Temperature (TBv) to the regression model. In general, all these variables can be classified into vegetation, temperature, soil wetness, topography, and soil factors and sensors conditions.

In recent years, the Chinese government has carried out afforestation activities in order to reverse desertification in the North. Considering the role of SM in the ecological environment, it is urgent to obtain accurate SM with high temporal and spatial resolution. This study aims to downscale SMAP SM products by constructing a nonlinear relationship between SM and related surface variables by means of multiple machine learning methods and generate SM products with higher temporal and spatial resolution in areas affected by desertification. The in situ observed SM data from the Maqu Monitoring Network and
Babao Monitoring Network and precipitation and temperature data from 131 meteorological stations were used for validation and analysis.

2. Materials and methodology

2.1 Study area

Northern China is mostly arid with an annual precipitation of less than 400 mm. The region belongs to the temperate continental monsoon climate and is subject to large-scale desertification. The desert areas of Northern China are susceptible to climate and hydrological changes and have fragile ecosystems. Soil water is a key parameter of the water-vapor-ecosystem, and its change greatly affects the survival of vegetation and agricultural production in areas affected by desertification. The studied area used for this study covers 3.36 million km², encompassing seven provinces. The terrain is complex, and the average elevation is approximately 1900 m, ranging from -192 m to 7439 m.

Figure 1: Location of the study area.

2.2 Observations for the production of soil moisture data

2.2.1 SMAP SM data

The SMAP satellite was launched on January 31, 2015. Its mission consists of an L-band radar and radiometer instrument suite, which provides global measurements and monitoring of SM in the top 5 cm of soil. The Level-3 products are daily
composites of the Level-2 products and are the most commonly used for applications. The Level-3 products are available in three spatial resolutions: 36 km passive, 9 km active-passive, and 3 km active (O’Neill et al., 2010). Following the malfunctioning of its radar in 2015, SMAP radar data were replaced with those of Sentinel-1, limiting the application of active and active-passive products.

The SMAP Level-3 passive daily SM product (L3_SM_P, Version 6) with a grid resolution of 36 km has been produced since March 31, 2015. Zeng et al. (2015) showed that most of remotely sensed SM products were slightly better during daytime than during nighttime, and the same conclusion for the SMAP SM product was confirmed by Zhao et al. (2018). Therefore, the SMAP Level-3 SM product with the descending overpass time of 6:00 AM was used in this study. The data were downloaded from NASA Earthdata (https://search.earthdata.nasa.gov).

2.2.2 MODIS products

MODIS provides continuous time-series predictors for important parameters, such as vegetation index and surface temperature. This paper used MODIS products MOD09A1, MOD11A1, MOD13A2, MOD15A2H and MCD43D58 (Table 2). The soil wetness related indexes, including NDWI, LSWI and NSDSI, were produced using bands of the MOD09A1 product. Their formulas are:

\[

da = (B_4 - B_2) / (B_4 + B_2)
\]

\[
b = (B_2 - B_6) / (B_2 + B_6)
\]

\[
c = (B_6 - B_7) / B_6
\]

where \(B_2\), \(B_4\), \(B_6\) and \(B_7\) represent the MOD09A1 surface reflectance of the 2nd, 4th, 6th and 7th bands, respectively.

These MODIS products are available from NASA Earthdata (https://search.earthdata.nasa.gov), and all data were obtained from 2015 to 2020.

2.2.3 Topographic data

Topographic factors are strongly related to SM, including elevation, slope and aspect. The Shuttle Radar Topography Mission (SRTM) digital elevation model (DEM) was used as elevation. Slope and aspect can be generated based on the DEM. These data were obtained from the Geospatial Data Cloud (http://www.gscloud.cn/), where slope and aspect have been processed and provided directly.

2.2.4 Soil texture data

Soil texture, the proportions of sand, silt and clay particles, controls the water holding capacity of the soil. The soil data used for this study used the China Soil Characteristics Dataset (CSCD) (Shangguan et al., 2012), obtained from National Tibetan Plateau Data Center (http://westdc.westgis.ac.cn/).

2.2.5 In Situ SM observations
The in situ SM measurements were collected from the data provided by the Maqu Monitoring Network (Zhang et al., 2020) and the Babao Monitoring Network (Kang et al., 2017). The Maqu Monitoring Network covers 26 sites and provides SM for the surface layer (0-5 cm) at 15-minute intervals from 2009 to 2019; 19 of the available sites which have data after 2015 were used in this study (Fig. 1). The Babao Monitoring Network covers 40 sites and provides hourly SM for the surface layer (4 cm, 10 cm and 20 cm) from 2013 to 2017; 29 of the available sites have data after 2015 and were used in this study (Fig. 1). To compare with the simulated results, they were all processed into daily time series.

### 2.2.6 Precipitation data

The precipitation data were acquired from 131 meteorological stations from the China Meteorological Data Service Centre (http://data.cma.cn). The spatial locations of these meteorological stations are shown in Fig. 1.

| Datasets | Predictors | Spatial resolution | Temporal resolution | Number of granules (Years×tiles) |
|----------|------------|--------------------|---------------------|----------------------------------|
| SMAP     | SM         | ~36 km             | Daily               | 2064                             |
| MOD11A1  | LST; EVI   | 1 km               | Daily               | 17460                            |
| MOD13A2  | NDVI; EVI  | 1 km               | 16-day              | 1104                             |
| MOD15A2H | LAI; FAPAR | 500 m              | 8-day               | 2208                             |
| MOD09A1  | NDWI; LSWI; NSDSI | 500 m | 8-day | 2208 |
| MCD43D58 | Albedo     | 30 Arcsec          | Daily               | 2192                             |
| SRTM     | DEM; Slope; Aspect | 90 m | - | 32 |
| CSCD     | Sand; Silt; Clay | 1 km | - | 1 |

### 2.2.7 Other gridded SM datasets

Some other gridded SM data were used to compare the simulation results (Table 3). The SMAP Level-2 product (L2_SM_SP) merges SMAP radiometer and processed Sentinel-1A/1B SAR observations. It is available at 3 km and 1 km resolutions. The Global Change Observation Mission Water (GCOM-W1) AMSR2 product is produced by the Japan Aerospace Exploration Agency (JAXA), and SM data at a 0.1° spatial resolution were selected for this study. The Copernicus Climate Change Service (C3S) produces a global SM gridded dataset from 1978 to present from satellite sensors such as SMOS, AMSR2 and SMAP. It has a spatial resolution of 0.25 degrees and offers three types of products: active, passive and combined. The combined product that we used in this study is generated by merging the active and passive products. The fifth generation ECMWF reanalysis dataset (ERA5) provides several variables including volumetric soil water over several decades. In the dataset, the soil is divided into four layers and the depth of the top layer is 0-7 cm. In this study, we downloaded the hourly volumetric soil water data of the top layer and processed them as daily averages. Famine Early Warning Systems Network (FEWS NET) Land Data Assimilation System (FLDAS) provides daily SM at a 0.01° spatial resolution over the Central Asia region (30-100° E, 21-56° N), which covers part of our study area. The product consists of four layers of SM, and the SM at the top layer (0-10 cm) was selected for this study.

| Institution | Name          | Soil layers | TYPES | Temporal resolution | Grid spacing | Data link |
|-------------|---------------|-------------|-------|---------------------|--------------|-----------|
|             |               |             |       |                     |              |           |

Table 3: The gridded SM products used in this study
### Data Sources

| Agency | Instrument | Layer | Resolution | Data Availability | Data Link |
|--------|------------|-------|------------|-------------------|-----------|

### 2.3 Downscaling approach based on multi-machine learning

According to the selected variable indicators (mainly including topographic data, soil data and some MODIS products) and machine learning methods, we constructed a framework to downscale SMAP SM based on multiple machine learning methods (Fig. 2).
2.3.1 Machine learning methods

Machine learning methods are widely used in regression and classification. We selected machine learning methods that are currently widely used to build regression models for SM and its related variables. We studied five methods: Multiple linear regression (MLR), support vector regression (SVR), artificial neural networks (ANN), random forest (RF) and extreme gradient boosting (XGB). MLR and SVR have been widely used as regression methods in the past (Yu et al., 2012; Achieng, 2019; Wang et al., 2019). ANN is currently one of the most popular machine learning methods and is used in many fields, including remote sensing of soil moisture inversion (Del Frate et al., 2003; Elshorbagy and Parasuraman, 2008; Yao et al., 2017; Chen et al., 2021).

RF and XGB are tree based ensemble algorithms, which have prediction accuracy and good generalization ability, and are not prone to overfitting (Rao et al., 2018; Abbaszadeh et al., 2019). RF is a multiple-tree algorithm improved by Bootstrap to reduce decision tree bias in determining the splits (Mohana et al., 2021). Many studies have used RF to build regression models of remotely sensed SM and related variables, and almost all achieved better results compared to other regression methods (Zhao et al., 2018; Qu et al., 2019; Hu et al., 2020). In contrast, the application of XGB, which applies a regularized
gradient boosting framework, is still very limited. However, XGB has incomparable advantages in generalization performance and accuracy (Wang et al., 2020). Compared with RF and other some methods, XGB has significantly faster calculation speed (Fan et al., 2018; Shi et al., 2021). Some studies have shown that XGB is a better regression and classification algorithm than RF and other machine learning methods (Ågren et al., 2021; Fan et al., 2021).

### 2.3.2 Downscaling process

The downscaling process is shown in Fig. 2. First, due to the difference in spatial resolution and data format, all required data were preprocessed. All selected variables, including LST, Albedo, LAI, NDWI, LSWI, NSDSI, NDVI, EVI, DEM, slope, aspect, sand, silt and clay, were aggregated into a resolution of 1 km with a geotiff format. These variables were further resampled to the spatial resolution of the SMAP SM data (36 km) using the nearest neighbor interpolation method. The regression model was then defined according to the selected machine learning method:

\[
SM = f(LST, Albedo, LAI, NDWI, LSWI, NSDSI, NDVI, EVI, \\
DEM, slope, aspect, sand, silt and clay)
\]  

where \( f \) represents the regression function of the machine learning method (MLR, SVR, ANN, RF or XGB).

Then, the regression model based on multiple machine learning was built. The MODIS products and SMAP SM data have different temporal resolutions. Since it is severely affected by noise (such as clouds), MOD11A1 only provides daily valid clear-sky LST values onto grids. The variables from MOD13A2 and MOD15A2H are the best composite within 16 days and 8 days, respectively. In addition, because each SMAP image has a narrow coverage, there may be few or no valid samples if only the data of a certain day are selected to build the regression. To overcome the limitation, we chose to build regression models within 16 day periods (the lowest temporal resolution from these dynamic variables). All valid data (including training and test datasets) within 16 days were used as the samples in the regression model. For instance, for NDVI and EVI on January 1, 2020, which are composite results from January 1 to January 15, the valid data during the period were used as samples. The number of valid samples for surface variables and SMAP SM for each period in 2015-2020 is shown in Fig. 3. Since there are fewer available SMAP SM grid data in the cold season, there may be few valid samples we can obtain for the period. Considering the number of samples is critical to the accuracy of the regression model, we only selected periods with more than 100 samples to build the model and DOY of 2016017, 2018017, 2018353, 2019001 and 2019177 were excluded. The valid samples were divided into a training set and a test set, each accounting for 50% of the total number of samples. Then, we used these samples and multiple machine learning methods (MLR, SVR, ANN, RF and XGB) to build a regression model for each 16-day period.
2.3.3 Evaluation method

The correlation coefficient (R) and the root mean square error (RMSE) were used to evaluate the accuracy of the regression model based on these machine learning methods (MLR, SVR, ANN, RF and XGB). They are calculated as:

\[ R = \frac{\text{Cov}(SM_I, SM_P)}{\sqrt{\text{Var}(SM_I)\text{Var}(SM_P)}} \]  

(5)

\[ \text{RMSE} = \sqrt{\frac{1}{n} (SM_P - SM_I)^2} \]  

(6)

where \( SM_I \) is the SMAP SM, \( SM_P \) is the corresponding SM predicted by the regression model, \( \text{Cov} \) represents the covariance function, \( \text{Var} \) is the variance, and \( n \) is the number of valid samples for \( SM_I \) or \( SM_P \).

The regression model with the smallest average RMSE of training and test datasets was selected as the optimal model.

\[ \text{RMSE} = \frac{\text{RMSE}_{\text{Training}} + \text{RMSE}_{\text{Test}}}{2} \]  

(7)

where \( \text{RMSE}_{\text{Training}} \) and \( \text{RMSE}_{\text{Test}} \) are the RMSE of the training set and test set for these models, respectively.

We used the selected optimal model with these surface variables with a resolution of 1 km within 16 days to simulate SM at 1 km resolution on the corresponding date. Taking 16 days as a period, we predicted all daily SM data with a spatial resolution of 1 km from 2015 to 2020. In addition, to obtain a more complete time series of SM data, we used the model of the previous period when the number of valid samples was less than 100.

The in situ SM measurements were used to validate the downscaled results. In addition to R and RMSE, unbiased RMSE (ubRMSE) and bias were also calculated according to:

\[ \text{ubRMSE} = \sqrt{\frac{1}{n} (\text{SM}_{in} - \overline{\text{SM}_{in}} - (\text{SM}_{D} - \overline{\text{SM}_{D}}))^2} \]  

(8)
\[ \text{bias} = \bar{SM}_{in} - \bar{SM}_D \]  

where \( SM_{in} \) is the in situ observed SM, \( SM_d \) is the downscaled SM of the corresponding grid, and \( n \) is the number of valid samples for \( SM_{in} \) or \( SM_d \).

### 3. Results

#### 3.1 Model comparison

The daily SM from DOY 81 in 2015 to DOY 366 in 2020 were simulated producing 128 regression results every 16 days. According to Equation 3, among the 128 regression results, there were 123 from the XGB model, and 5 from RF (including DOY 2015241, 2016161, 2016209, 2017241 and 2017257).

The correlation coefficient (R) and the root mean square error (RMSE) of each regression result for the training set and the test set are shown in Fig. 4 and Fig. 5, respectively. For all models, R is greater than 0.8 and RMSE is less than 0.1 both for the training and the test set. For the training set using XGB, Rs are all above 0.96, generally higher than for other methods; Similarly, the RMSEs of XGB are all lower than 0.02, generally lower than those of other methods. The R of RF is second only to that of XGB, and for some periods it is higher than for XGB; the RMSEs of RF are also generally lower than 0.02 and are lower than those of XGB in some periods. SVR and ANN perform better in the cold season, and worse in other seasons. In general, their results are inferior to those of XGB and RF. The simulation results of MLR are relatively poor both in terms of RMSE and R.

The results of the test set show that XGB, RF and SVR perform better than ANN and MLR, and are better in the cold season. Table 4 shows the average RMSE and R values of the training and test sets over all periods, and the performance order of the model can be obtained as XGB>RF>SVR>ANN>MLR.
Figure 4: The correlation coefficient (R) of the models (MLR, SVR, ANN, RF and XGB) on different periods: (a) The training accuracy; (b) The test accuracy.

Figure 5: The root mean square error (RMSE) of the models (MLR, SVR, ANN, RF and XGB) for different periods: (a) The training accuracy; (b) The test accuracy.

Table 4: Accuracy of the models based on correlation coefficient (R) and root mean square error (RMSE)

| Model   | Training set |   |   |   |   |   |
|---------|--------------|---|---|---|---|---|
|         | RMSE         | MLR | SVR | ANN | RF | XGB |
|         | R            | 0.042 | 0.032 | 0.028 | 0.013 | 0.010 |
| Test set| RMSE         | 0.043 | 0.029 | 0.047 | 0.030 | 0.029 |

3.2 Comparison with the in situ data and precipitation

To evaluate the performance of the downscaling approach, the downscaled 1 km gridded SM were compared with the in situ SM observations. The SM before and after downscaling were both compared with the in situ SM data of the Maqu Network and Babao Network (Fig. 6). Due to the difference in sensors, soil depth and measurement scale (point observation in case of the in situ measured SM and 1 km grid for the downscaled SM), there is a certain deviation between in situ observation data and the downscaled gridded SM data. The downscaled SM of most sites at the Maqu Network are highly correlated with the in situ measured SM (R>0.6). The ubRMSEs with an average of 0.049 m³/m³ are all less than 0.073 m³/m³, and the bias ranges from -0.10 to 0.15 m³/m³. The comparative results of the Babao Network are not as good as that of the Maqu Network. The SM data of most sites at the Babao Network have larger ubRMSE and bias, and the correlation coefficients between in situ observed SM and the downscaled SM are generally lower. That may be mainly because the measured soil depth at the Babao Network is 4 cm, which means that there could be a systematic error between the datasets.
Figure 6: The relationships between in situ SM and downscaled SM. (a) Maqu Network; (b) Babao Network.

To better understand the reason for these poor results, the scatter plots comparing the two sets of data were drawn. Figure 7 shows the results of the 19 sites of the Maqu Network. All four statistical metrics, namely, R, RMSE, ubRMSE and bias were calculated, and their fitting line of the scatter was also plotted. Not surprisingly, the relationship is generally improved where there are more points. The same conclusion can be drawn according to Fig. S1, which shows the comparative results of 29 sites at the Babao Network.
Figure 7: Comparison between the downscaled SM and in situ SM of the Maqu Network.

The observed SM of sites with a greater number of observed data were compared with these gridded SM data at different resolutions and precipitation. Figure 8 shows the temporal variations of these SM at four sites. The relationship between in situ observed SM and precipitation at all four sites is very consistent, showing annual fluctuation. The greater SM corresponds to more precipitation during the hot season, and the smaller SM corresponds to less precipitation during the cold season.

Except for GCOMW/ASMR2 SM, the variation trends of these acquired gridded SM and the downscaled SM are basically the same despite the large difference in spatial resolution. GCOMW/ASMR2 significantly underestimates SM compared to other products. Both the SMAP L2 SM at 1 km and 3 km are overestimated compared with in situ observations. Moreover, SMAP L2 SM has some valid data mainly on hot days and almost no valid data during cold seasons. The peak values of the ERA5 SM are close to those of the in situ observations, but the low values are overestimated. The C3S SM is similar to the 36 km SMAP SM, and its peak values are simulated more accurately, while the minimum values have little valid data. Compared with the original data (36 km SMAP L3), the downscaled SM has a more complete time series, especially during the cold season.
season. The downscaled SM data almost all match well with the in situ measured SM data, and all of them are also consistent with the precipitation. The difference between the downscaled SM and the in situ measured SM is mainly reflected in the magnitude of the variation, which is probably due to the difference in spatial resolution.
Figure 8: Time series of the in situ observed SM, the downscaled SM, the acquired gridded SM products and daily precipitation at the four selected SM sites (From Maqu Network and Babao Network, respectively).
3.3 Mapping of the downscaled SM

SM varies greatly in different months in desertified areas. Figure 9 shows the average SM in each month in the study area. The SM shows a monthly change pattern, and the values from June to September are bigger than in other months, especially in southern Qinghai Province, eastern Inner Mongolia Province, and western Xinjiang Province, which is consistent with the process of vegetation growth. The SM in some areas is low throughout the year, such as in the Tarim Basin of Xinjiang Province, western Inner Mongolia Province and most of Gansu Province.

![Figure 9: Monthly average SM in the study area.](https://doi.org/10.5194/essd-2021-362)

The annual average SM was also calculated (Fig. S2). Overall, there is little variation in SM in different years. Further, we compared the spatial patterns of the downscaled SM with the gridded SM products with different resolutions. Figure 10 shows the daily average SM of these products from 2015 to 2020. The spatial patterns of the downscaled SM and 36 km SMAP SM are basically consistent, but the downscaled data show better details in some areas such as near rivers. The overall values of GCOMW SM are relatively small, and exhibit some obvious errors in some areas. For example, SM in the Tarim Basin is higher than in the surrounding area, which is completely inconsistent with other SM data. The spatial pattern of the C3S SM
is close to the downscaled SM and the 36 km SMAP SM, but some details are not presented. For example, SM in the Hetao Plain along the Yellow River is much higher than that in its surrounding area, which can be found in the downscaled SM and the SMAP SM, but not in the C3S SM. The average SM of the ERA5 products is polarised. In some areas the values are very large, and in some small areas they are very small. The FLDAS SM has high resolution, and its overall spatial pattern is relatively consistent with the downscaled SM and 36 km SMAP SM. The difference is that the FLDAS SM is significantly larger in higher elevation areas of the west than in other regions, which is quite different from other products. This suggests that the FLDAS SM may be overestimated in these regions. In addition, FLDAS SM does not show wetter soil along the river.

Figure 10: Daily average SM from 2015-2020 in the study area. (a)-(f) are the downscaled SM (1 km), SMAP L3 SM (36 km), GCOMW/ASMR2 SM (0.1°), C3S SM (0.25°), ERA5 SM (0.1°) and FLDAS SM (0.1°), respectively.

To better demonstrate the differences in SM, a case of the Mu Us Desert was selected (Fig. 11). The Mu Us Desert is located in a semi-arid area with annual average precipitation of generally less than 400 mm, decreasing gradually from southeast to northwest. The main types of land cover are grassland and sandy land, and the salinization is serious in a few areas. Desertification has been severe for a long time in the past but has been significantly reversed with artificial afforestation in recent years.

SM shows an overall trend of gradual decrease from the southeast to the northwest (Fig. 11 (b)~(g)), which is consistent with the distribution of precipitation. The average SM of the same location changes little from year to year. Overall, it is relatively large in 2018 and relatively small in 2015, which is also roughly consistent with annual precipitation patterns. Land cover types also have a certain influence on the spatial difference of SM. The northwestern portion of the Mu Us Desert is mainly grassland, which is strongly dependent on precipitation (Fig. 11 (h)). The southeastern area is mainly cultivated land and is less affected by precipitation as it relies on pumping groundwater rather than natural precipitation (Fig. 11 (j)).
Figure 11: Soil moisture estimated for the Mu Us Desert. (a) Land cover distribution over the study area; (b)-(g) annual average SM from 2015-2020; (h)-(j) annual precipitation and annual average temperature of three sites (53529, 53723 and 53740), whose surroundings are mainly grassland, cultivated land, and cultivated land, respectively.

4. Discussion

4.1 Regression variable importance

The selection of variables is an important step of a nonlinear regression model. The importance analysis of the variables carried out for this research found that a larger number of variables can improve the regression effect of these models to some extent. Figure 12 shows the average importance scores of each variable for the RF and XGB models across all available days.
The importance scores of different variables in the RF based model and the XGB based model are similar. LST and surface albedo both affect surface energy exchange and partition. LST is a very important variable in both models, which is consistent with the study of Zhao et al. (2018). NSDSI is the most sensitive soil moisture index compared to LSWI and NDWI, which was demonstrated in Yue et al. (2019). Topographical factors also exhibit importance on SM, especially elevation. The influence of soil texture (sand, silt, and clay) is relatively weak, but it cannot be completely ignored.

The standard deviation of the importance scores of each variable is shown with error bars in Fig. 12. Its changes are mainly affected by the samples used in the regression model and the temporal variations in surface variables. For static variables such as soil structure and topographic factors, the changes in their importance scores mainly depend on the number and the location of the samples. Figure 12 also shows that their standard deviation is relatively small. Compared with static variables, the standard deviation of the importance scores of dynamic variables is significantly larger, especially for LST and LAI. This indicates that it is not reliable to construct a single regression model for a long time series.

In general, the variable importance analysis suggests that the selected variables are suitable for the construction of the regression model. Moreover, choosing 16 days as a time period to build a regression model benefits from obtaining a sufficient number of samples, especially since the surface variables were found still unchanged during these intervals.

![Variable Importance Diagram](image)

**Figure 12:** The average importance scores of variables for the RF based approach and XGB based approach. Note: The importance scores are presented by IncNodePurity where the sum value is normalized for the RF model; The XGB model uses Gain to reflect the weight of variables.

### 4.2 Advantages of model combination

The simulation results of long time series will inevitably suffer the interference of various noises. A combination of multiple methods can reduce overfitting and uncertainties (Zanotti et al., 2019; Yu et al., 2021). The five methods (MLR, SVR, ANN, RF, and XGB) in this study have indicated the potential flaws of a single model. Although XGB generally perform better than other models, it still has still some shortcomings. As it can be seen from Figs. 4 and 5, compared with the training accuracy,
the test accuracy of the XGB model is significantly reduced in several periods. This means that the simulation results of the XGB model is likely to have a certain degree of overfitting. In contrast, the difference between training accuracy and test accuracy of the RF model is even smaller. It showed better stability than XGB at some periods (Figs. 4 and 5). The training accuracy of MLR and SVR has a small difference from the test accuracy, but the overall accuracy is obviously lower, which is not suitable for remote sensing SM prediction (Table 4). Some studies have also proved that SVR may also perform better than some ensemble algorithms (Yu et al., 2012; Fan et al., 2018). The fitting effect of ANN varies greatly in different periods, indicating that its generalization is lower than other models (Piotrowski and Napiorkowski, 2013). In general, the XGB and RF models provide the best combination of prediction accuracy and stability.

4.3 Analysis of the relationship with precipitation and temperature

Precipitation and temperature are important factors affecting SM. To evaluate the impact of precipitation and temperature on SM, we performed a partial correlation analysis on the data of all meteorological stations. Figure 13 shows that SM is mainly positively correlated with precipitation and temperature, and a few regions are significantly negatively correlated with temperature. In terms of spatial distribution, SM of the sites in the eastern region (including Inner Mongolia Province, Hebei Province and Shanxi Province) is mainly significantly affected by precipitation. Due to the influence of glaciers and snowmelt, the SM of the sites in the western region (Xinjiang Province and Gansu Province) is more affected by temperature. In addition, the number of sites with significant positive correlation with precipitation and temperature is the largest in Qinghai Province. This indicates that precipitation and temperature in the eastern part of the Tibetan Plateau both have a great influence on SM.

4.4 Uncertainty and Prospects
While this study greatly improved the spatial resolution of SM data from 2015-2020 in the desertifying areas of North China by downscaling SMAP SM products, it still presents some shortcomings. For example, due to the image quality and coverage of SMAP and the impact of noise from clouds on the MODIS products, the number of valid samples for a 16-day period may still be less than 100 points. This study replaced the periods with less than 100 samples with the model of the previous periods. Due to the limited number of available samples, the simulation in the cold season is relatively poor (Fig. 8). In addition, the upscaling (from 1 km to 36 km resolution) of surface variables also has a certain impact on the accuracy of the model.

The Chinese government focuses on desertification reduction through afforestation and the establishment of grasslands. SM data with high temporal and spatial resolution can provide a reference for the next steps of revegetation.

5 Code and data availability

The codes mainly used in this paper mainly includes sample selection, the building of the optimal regression model and the result prediction. These codes based on the R language can be found in the supplementary documents. The downscaled daily SM dataset at 1 km spatial resolution is available at https://doi.org/10.6084/M9.FIGSHARE.16430478.V5 (Rao et al., 2021). The data maps are all provided in Geotiff format, and the value has expanded 10,000 times to make them easier to store. The filenames reflect the production date in Julian Day format.

6 Conclusions

In this study, a framework was proposed for downscaling 36 km SMAP SM products using MODIS optical products and other surface variables (mainly topographic data and soil data) based on multiple machine learning methods. Overall, the regression performance of the five methods is, in order: XGB>RF>SVR>ANN>MLR. Compared with MLR, SVR and ANN, XGB and RF have much better regression accuracy, and they were used in combination to produce daily 1 km downscaled SM in a period of 16 days. The validation shows that the downscaled SM are highly related to most in situ measured SM. The ubRMSE with an average of 0.049 m$^3$/m$^3$ is generally less than 0.073 m$^3$/m$^3$ at the Maqu Network. Time series of SM data from in situ observation sites are also compared. The results show that the downscaled SMs are highly related to SMAP SMs, and provide a more complete time series and match better with the in situ measured SM. Compared with some commonly used gridded SM products such as SMAP L2 (1 km or 3 km), GCOMW/ASMR2, C3S, ERA5 and FLDAS SMs, the downscaled SM data not only have higher spatial resolution, but also have a more reliable accuracy whether in time series or spatial distribution.

The maps of downscaled SM show larger values from June to September, which coincides with the vegetation growing season. The difference in annual mean SM is small. Spatially, SM is relatively large in Qinghai Province and in northeastern Inner Mongolia, especially in summer. In arid areas such as the Tarim Basin, SM is relatively small throughout the year.
Moreover, precipitation and temperature both have a great influence on SM in the study area. Precipitation has a greater impact on SM in the eastern part of the study area, while the effect of temperature appears to be more pronounced in the west. This approach makes it possible to more accurately assess the soil moisture status in the study area. The results can support regional agricultural planting and revegetation efforts and can be applied to limit desertification in other areas in the future.
