Abstract. The article shows that the productivity of spring wheat is determined by the total effect of a set of conditions, each of which affects the amount of products obtained. As a result of the research, it was found that the yield of spring wheat directly depends on the hydrothermal conditions of the growing season. The key factor affecting the increase in the productivity of crops when using mineral fertilizers is the amount of precipitation during the growing season. The use of mineral fertilizers can significantly increase the yield of spring wheat, reducing the negative effect of the hydrothermal conditions of the growing season. So, when N₆₀P₃₀K₆₀ was introduced, the yield increase in different climatic conditions of the research years was 9,3 ... 92,8%. It was also found that the reproductive function of durum spring wheat is characterized by the fact that the total number of caryopses of a shoot spike and their total weight are in close proportional dependence on the value of its vegetative mass. In this case, the value of the grain-straw ratio is a consequence of the proportional dependence of the reproductive elements of the shoot (acceptors) of wheat on the size of its vegetative (donors) organs.

1 Introduction

Spring wheat is a widely cultivated crop in the world, therefore, scientific research devoted to the issues of obtaining stable yields of this crop is carried out in many countries [1-10]. Wheat yield is formed under the influence of a complex set of conditions, each of which affects its quantity and quality. In the future, due to global warming, the importance of temperature and water regimes will grow [11-14]. Analysis of the elements of the crop, which determine its size and quality, makes it possible to more fully reveal the interaction between wheat plants and the environment in different periods of the growing season and, on this basis, draw up a cultivation technology taking into account the soil and climatic conditions of the region.

One of the indicators allowing to determine the supply of plants with moisture is the hydrothermal coefficient [15]. The ratio of the weight of a plant grain to its aboveground vegetative mass is a specific indicator. It expresses the measure in which a unit of

vegetative mass produces grain. The higher the numerical value of the indicator, the higher
the individual plant productivity.

Therefore, studies on the influence of the hydrothermal coefficient on the yield and on
the reproductive function of the shoot from the standpoint of the donor-acceptor relations of
its reproductive and vegetative organs, which underlie the biology of a cereal plant and
determine the level of its productivity, are currently isolated and relevant.

2 Materials and methods

The studies were carried out in the Aksai district of the Rostov region on the experimental
field of the Federal Scientific Rostov Agrarian Center. The object of research is spring
wheat. The soil of the experimental site is represented by ordinary chernozem, the
granulometric composition is heavy loamy, in places light loamy. The thickness of the
humus horizon is 75 - 100 cm, the humus content is 3,6 – 4,0%. The content of gross
nitrogen – 0,22 – 0,24, total phosphorus – 0,17 – 0,18, potassium – 2,3 – 2,4%, mineral
nitrogen and mobile phosphorus - low, exchangeable potassium - increased. The climate of
the zone is continental, moderately hot. The annual air temperature averages 9,6 °C, the
sum of temperatures is 3200–3400 °. The duration of the warm period is 230-260 days, the
frost-free period is 175-180 days. The average annual precipitation is 500 mm, during the
warm period, it falls up to 300 mm.

Fertilization scheme: I - control (without fertilizers) II - N60, III - P30, IV - K30, V
- N60P30, VI - N30, VII - N60K60, VIII - P30K60, IX - N60P30K60. Phosphate fertilizers and
potassium - KCl (60%) were applied for the main treatment, nitrogen fertilizers
- for the
main one and for top dressing in the form of ammonium nitrate (34,5%) in the tillering and
tube emergence phase. The setting of experiments, accounting and mathematical processing
of the data obtained were carried out according to B.A. Dospekhov. Agrotechnics are
generally accepted for the zone. The method of placing plots is systematic. The repetition
is threefold. The calculation of the hydrothermal coefficient was carried out according to G.T.
Selyaninov. The selection of sheaves and their analysis were carried out according to the
generally accepted methodology in crop production. The method of systemic
morphogenetic study of wheat plants based on the species of the VIR collection was
developed and published.

3 Results

The Rostov region belongs to the zone of unstable moisture, which makes the amount of
precipitation a factor that determines the yield of any agricultural crop. One of the
indicators allowing to determine the supply of plants with moisture is the hydrothermal
coefficient.

Analysis of the hydrothermal coefficient of the growing season of spring wheat from
2007 to 2018 showed that the growing season of 2007, 2013 and 2018 (Fig. 1)
characterized as dry, 2009 - very dry, two years 2008 and 2012 were arid, four were slightly
arid (2010, 2014, 2016 and 2018). In dry years, the amount of precipitation that fell during
the growing season of the studied crop did not exceed 60 mm, and the value of the HTC
ranged from 0,19 to 0,31. 2011 and 2015 were characterized by the highest moisture
supply. During the growing season of spring wheat, 240,5-248,0 mm of atmospheric
precipitation fell, while the sum of effective temperatures ranged from 1590 to 1749 °C,
and the GTC was in the range of 1,38-1,56.
Fig. 1. Hydrothermal indicators of the growing periods of spring wheat during the years of research.
The most accurate indicator characterizing the effectiveness of the use of one or another agricultural technique is the yield of the cultivated crop. During the research period, the introduction of mineral fertilizers significantly increased the yield of spring wheat (Table 1).

| Option       | Research year |
|--------------|---------------|
|              | 2007  | 2008  | 2009  | 2010  | 2011  | 2012  | 2013  | 2014  | 2015  | 2016  | 2017  | 2018  |
| The control  | 15.1  | 24.8  | 18.6  | 25.0  | 15.3  | 11.1  | 17.6  | 23.6  | 24.1  | 16.9  | 16.2  |

| P30K60       | 17.9  | 24.6  | 23.7  | 23.8  | 33.2  | 25.5  | 17.7  | 17.9  | 30.7  | 31.2  | 23.6  | 20.2  |
| N60P30K60    | 16.8  | 25.8  | 22.0  | 22.9  | 28.6  | 23.3  | 18.5  | 16.2  | 29.6  | 30.1  | 21.8  | 18.2  |
| LSD 0.05     | 1.8   | 2.4   | 1.9   | 1.5   | 2.1   | 2.7   | 2.4   | 3.3   | 2.2   | 2.4   | 1.7   | 2.1   |

The yield, depending on the application of fertilizers and the year of research of the studied crop, varied widely (from 11.1 to 35.8 c/ha). The use of mineral fertilizers led to a significant increase in the yield of spring wheat, an increase with the introduction of N60P30K60 made it possible to increase the yield by 9.3 … 92.8%.

The calculation of the multiple correlation coefficient showed that in the non-fertilized version, there is a direct average relationship between the yield of spring wheat, the amount of precipitation and the SCC, and there is a weak inverse relationship between the amount of active temperatures (Table 2).

| Indicators                          | The control | N60 | P30 | K60 | N60P30 | N60K60 | P30K60 | N60P30K60 |
|------------------------------------|-------------|-----|-----|-----|--------|--------|--------|-----------|
| Amount of precipitation, mm        | 0.63        | 0.82| 0.80| 0.80| 0.82   | 0.86   | 0.85   | 0.81      |
| The sum of active temperatures, °C | -0.37       | -0.60| -0.42| -0.42| -0.55  | -0.58  | -0.53  | -0.63     |
| HTC                                | 0.64        | 0.84| 0.79| 0.79| 0.84   | 0.88   | 0.86   | 0.84      |

The use of mineral fertilizers led not only to an increase in the yield of spring wheat, but also to an increase in the dependence of this indicator on the meteorological conditions of the growing season. So, on the variant with the use of fertilizers at a dose of N60P30K60, a close direct relationship was observed between the yield, the SCC and the amount of precipitation (r = 0.81), while the relationship between the yield and the sum of active temperatures was inverse and average in effect (r = -0.63).

Thus, the yield directly depended on the hydrothermal conditions of the growing season, and the key factor affecting the increase in crop productivity when using mineral fertilizers was the amount of precipitation during the growing season.
Differences in the hydrothermal parameters of the growing season had a significant effect on the yield of spring wheat, both in the control and in the variants with the use of mineral fertilizers. So, in the years with the poorest moisture supply (HTC up to 0,4), the yield of the studied crop in the control variant averaged 14,8 c / ha. With the growth of the hydrothermal coefficient, the yield increased. In the years with the GTC equal to 0,7-1,0, this indicator averaged 20,1 c / ha, and in the wettest years – 24,3 c / ha. A similar trend was noted for the variants with the use of mineral fertilizers.

Even with a critically low amount of precipitation of spring wheat during the growing season, which does not allow plants to efficiently use nutrients from the applied fertilizers, i.e. in years with HTC equal to 0,19 ... 0,31 (2007, 2013 and 2018), significant differences were noted in the effectiveness of the use of complete mineral fertilizer at a dose of N₆₀P₃₀K₆₀.

Since there is a direct strong relationship between the yield, hydrothermal coefficient (HTC) and the amount of precipitation in the fertilized variants, a regression analysis of these values was carried out. The plots constructed according to the regression equation between the two variables show that the increase in yield by applying N₆₀ by 71,9% depends on the value of the hydrothermal coefficient (Fig. 2). The influence of the amount of precipitation was 68,6%.

With the combined use of nitrogen and potash fertilizers in a dose of 60 kg of active ingredient, the dependence of yield on the hydrothermal coefficient increased to 71,3%, and on the amount of precipitation up to 67,4% (Fig. 3).
With the combined use of nitrogen and phosphorus fertilizers at a dose of N_{60}P_{30}, the above indicators increased to 77.4% and 73.5%, respectively (Fig. 4).

With the introduction of full mineral fertilizer at a dose of N_{60}P_{30}K_{60}, the influence of the hydrothermal coefficient and precipitation on the yield decreased, amounting to 69.8 and 65.7%, respectively (Fig. 5). This effect was presumably associated with a more efficient water consumption by wheat plants when using a complete mineral fertilizer, which made it possible to reduce the consumption of productive moisture for the formation of a crop unit.
The ratio of the weight of a plant grain to its aboveground vegetative mass is a specific indicator. It expresses the measure in which a unit of vegetative mass produces grain. The higher the numerical value of the indicator, the higher the individual plant productivity. The conducted studies of the reproductive function of wheat and their wild-growing ancestors by the vegetative method showed that the total number of caryopses of a spike and their total weight are in close proportional dependence on the value of the vegetative mass of the shoot. Subsequent studies have shown that when growing in natural conditions of the field, such a relationship also takes place in durum wheat plants in different years (Fig. 6, 7).

**Fig. 5.** Dependence of the yield of spring wheat on the HTC (a) and the amount of precipitation that fell during the growing season (b) when applying \( N_{60}P_{30}K_{60} \).

![Graphs showing the relationship between HTC and productivity, and precipitation and productivity.](image)

**Fig. 6.** Dependence of the total number of spike grains (n) and their total weight (Y) on the vegetative (leaves, internodes, spikelet, spike, scales, awn) shoot mass (X) in durum spring wheat varieties in the full ripeness phase ... 2003 year.

![Graphs showing the relationship between the number of caryopses, ear grain weight, and aboveground vegetative mass.](image)
Fig. 7. Dependence of the total number of spike grains (n) and their total weight (Y) on the vegetative (leaves, internodes, spikelet, spike, scales, awn) shoot mass (X) in durum spring wheat plants at full ripeness. 2009 year.

An analysis of three-year experimental data given in Table 3 shows that with different total weights of sheaves in the control variant and the variant with mineral fertilizer at a dose of N$_{60}$P$_{30}$K$_{60}$, the ratio of grain to straw in them really remains in a very narrow range of numerical values (0,57- 0,65).

Table 3. Ratio of grain-straw in spring durum wheat plants of the cultivar on the control and fertilized variants on ordinary chernozem according to the precursor of alfalfa, 2009-2011.

| Year | The control | $N_{60}$P$_{30}$K$_{60}$ |
|------|-------------|-------------------------|
|      | weight sheaf, g | weight grains, g | weight straw, g | g/s | weight sheaf, g | weight grains, g | weight straw, g | g/s |
| 2009 | 65 | 25 | 40 | 0,62 | 76 | 30 | 46 | 0,65 |
| 2010 | 55 | 20 | 35 | 0,57 | 88 | 33 | 55 | 0,60 |
| 2011 | 51 | 20 | 31 | 0,64 | 84 | 31 | 53 | 0,58 |

Note: g/s is the ratio of grain mass to straw mass.
4 Conclusions

The yield of spring wheat directly depends on the hydrothermal conditions of the growing season. The key factor affecting the increase in the productivity of crops when using mineral fertilizers is the amount of precipitation during the growing season.

The use of mineral fertilizers can significantly increase the yield of spring wheat, reducing the negative effect of the hydrothermal conditions of the growing season. With the introduction of a complete mineral fertilizer in a dose of $N_{60}P_{30}K_{60}$, the yield increase in different hydrothermal conditions of the research years was 9.3% ... 92.8%.

In durum spring wheat of the variety, the reproductive function is characterized by the fact that the total number of caryopses of a shoot spike and their total weight are in close proportional dependence on the value of its vegetative mass. The grain-straw sheaf ratio reflects the proportional nature of the relationship between the reproductive and vegetative elements of the wheat shoot and is its natural consequence.
