ABSTRACT

In this paper, we present a multi-color photometric study of the nearby spiral galaxy M81, using images obtained with the Beijing Astronomical Observatory 60/90 cm Schmidt Telescope in 13 intermediate-band filters from 3800 to 10000 Å. The observations cover the whole area of M81 with a total integration of 51 hours from February 1995 to February 1997. This provides a multi-color map of M81 in pixels of 1″.7 × 1″.7. Using theoretical stellar population synthesis models, we demonstrate that some BATC colors and color indices can be used to disentangle the age and metallicity effect. We compare in detail the observed properties of M81 with the predictions from population synthesis models and quantify the relative chemical abundance, age and reddening distributions for different components of M81. We find that the metallicity of M81 is about $Z = 0.03$ with no significant difference over the whole galaxy. In contrast, an age gradient is found between stellar populations of the central regions and of the bulge and disk regions of M81: the stellar population in its central regions is older than 8 Gyr while the disk stars are considerably younger, $\sim 2$ Gyr. We also give the reddening distribution in M81. Some dust lanes are found in the galaxy bulge region and the reddening in the outer disk is higher than that in the central regions.

Subject headings: galaxies: abundances – galaxies: evolution – galaxies: individual (M81) – galaxies: stellar content – (ISM:) dust, reddening
1. INTRODUCTION

Spatially resolved information about the age, metallicity and interstellar medium reddening of galaxies is a powerful tool to study galaxy evolution since it provides essential clues in star formation history, chemical composition and enrichment history and environment of galaxies (Buzzoni 1989). To obtain such information, we need to know the stellar component and the overall properties of stellar populations (Leitherer & Heckman 1997). Ideally one would like to study resolved individual stars in galaxies. However, given the limited spatial resolution of current telescopes, this is only possible for a few very nearby galaxies. As a result, the stellar content of even some relatively simple galaxies remain to be unraveled (Thuan 1991). Information of stellar population and star formation history in these galaxies, however, can still be obtained from studying the integrated properties of the stars (e.g. Schmitt et al. 1996, Goerdt & Kollatschny 1998).

Since the pioneering work of Tinsley (1972) and Searle et al. (1973), evolutionary population synthesis has become a standard technique to study the stellar populations of galaxies. This is a result of improvements in the theory of the chemical evolution of galaxies, star formation, stellar evolution and atmospheres, and the development of synthesis algorithms and the availability of various evolutionary synthesis models. A comprehensive compilation of such models was published by Leitherer et al. (1996) and Kennicutt (1998). Widely used models include those from the Padova and Geneva group (e.g. Schaerer & de Koter 1997, Schaerer & Vacca 1998, Bressan et al. 1998, and Chiosi et al. 1998), GISSEL96 (Charlot & Bruzual 1991, Bruzual & Charlot 1993, Bruzual & Charlot 1996), PEGASE (Fioc & Rocca-Volmerange 1997) and STARBURST99 (Leitherer et al. 1999).

Many previous studies of integrated stellar populations use spectroscopic data, usually for limited regions in galaxies. In this paper, we will, instead, use multi-color photometry to probe the stellar populations. The multi-color photometry provides accurate spectral energy distributions (SEDs) for the whole galaxy, although at low spectral resolution. We shall demonstrate that it is a powerful tool to study the structure and evolution of the galaxy together with the theoretical evolutionary population synthesis methods (for an application of a similar technique with, but with fewer colors, to moderate redshifts, see Abraham et al. 1999). For this purpose, we pick M81 as the first application of this multi-color approach.

M81 is an excellent candidate because it is a nearby early-type Sab spiral galaxy at a distance of 3.6 Mpc and with an angular size of $\sim 26'$. The angular extent is large enough such that the disk and bulge regions are well separated from the ground. It has been the subject of numerous previous studies providing a wealth of information with which to compare the new metallicity and internal reddening distribution. The internal reddening has been studied by Kaufman et al. (1987, 1989), Devereux et al. (1995), Ho et al. (1996) and Allen et al. (1997). The metallicity has been studied by Stauffer & Bothun (1984), Garnett & Shields (1987), Brodie & Huchra (1991) and Perelmuter et al. (1995). In this paper, we present a further detailed
The outline of the paper is as follows. Details of observations and data reduction are given in section 2. In section 3, we provide a brief description of the model, and analyze the evolution of the integrated colors, color indices with age and metallicity. The observed two-dimensional spectral energy distributions (SEDs) of M81 were analyzed using stellar population synthesis models of Bruzual & Charlot (1996). The distributions of metallicity, age and interstellar reddening are given in section 4. In section 5, we discuss how different star formation histories and stellar population synthesis models change our results, and compare our results with previous studies. The conclusions are summarized in section 6.

2. OBSERVATIONS AND DATA REDUCTION

2.1. CCD Image Observation

The large field multi-color observations of the spiral galaxy M81 were obtained in the BATC photometric system. The telescope used is the 60/90 cm f/3 Schmidt Telescope of Beijing Astronomical Observatory (BAO), located at the Xinglong station. A Ford Aerospace 2048×2048 CCD camera with 15µm pixel size is mounted at the Schmidt focus of the telescope. The field of view of the CCD is 58′ × 58′ with a pixel scale of 1′′.7.

The multi-color BATC filter system includes 15 intermediate-band filters, covering the total optical wavelength range from 3000 to 10000Å (see Fan et al, 1996). The filters were specifically designed to avoid contamination from the brightest and most variable night sky emission lines. A full description of the BAO Schmidt telescope, CCD, data-taking system, and definition of the BATC filter systems are detailed elsewhere (Fan et al. 1996, Chen et al. 2000). To study the age, metallicity and interstellar reddening of M81, the images of M81 covering most part of the optical body of M81 were accumulated in 13 intermediate band filters with a total exposure time of about 51 hours from February 5, 1995 to February 19, 1997. The CCD images are centered at RA = 09h55m35s.25 and DEC=69°21′50″.9 (J2000). The dome flat-field images were taken by using a diffuse plate in front of correcting plate of the Schmidt telescope. For flux calibration, the Oke-Gunn primary flux standard stars HD19445, HD84937, BD+26°2606 and BD+17°4708 were observed during photometric nights. The parameters of the filters and the statistics of the observations are given in Table 1.

2.2. Image data reduction

The data were reduced with standard procedures, including bias subtraction and flat-fielding of the CCD images, with an automatic data reduction software named PIPELINE 1 developed for the BATC multi-color sky survey (Fan et al. 1996). The flat-fielded images of each color were combined by integer pixel shifting. The cosmic rays and bad pixels were corrected by comparison of multiple images during combination. The images were re-centered and position calibrated using the HST Guide Star Catalogue. The sky background of the images was obtained by fitting image areas free of stars and galaxies using the method described in Zheng et al. (1999). The absolute flux of intermediate-band filter images was calibrated using observations of standard stars. Fluxes as observed through the BATC filters for the Oke-Gunn stars were derived by convolving the SEDs of these stars with the measured BATC filter transmission functions (Fan et al. 1996). Column 6 in Table 1 gives the zero point error, in magnitude, for the standard stars in each filter. The formal errors we obtain for these stars in the 13 BATC filters is $\lesssim 0.02$ mag. This indicates that we can...
define the standard BATC system to an accuracy of \( \lesssim 0.02 \) mag.

After background subtraction, the standard deviation of the background for each image is 2.0ADU. Because the signal-to-noise ratio decreases from the center to the edge of the galaxy, we smoothed the images with a boxcar filter. The window sizes of the boxcar were selected depending on the ADU values of the BATC10 band image (7010Å). If the ADU value was less than 100, the pixel was set to zero; if the value was higher than 100, the pixel was adaptive-smoothed by boxcar filter of \( N \times N \) (cell size), where \( N = \min(151 / \sqrt{\text{ADU}_{\text{BATC10}}}, 15) \). By this method, the images were smoothed depending on the S/N of each cell. In the central area of M81, the original pixels were used, whereas near the edge of M81 the mean value of multiple pixels (cells) were used, as a result, the spatial resolution decreased from center to outer edge. The background errors before and after smoothing are given in the last two columns in Table 1.

Finally, the flux derived at each point of M81 is listed in Table 2[2]. The results provide a two-dimensional spectral energy distributions (SED) for M81. The ADU number of each image were converted into units of \( 10^{-30} \text{ergs}^{-1}\text{cm}^{-2}\text{Hz}^{-1} \). As an example, we present some SEDs for the different areas of M81 in this paper. The table gives the following information: Column 1 and Column 2 give the \((X, Y)\) positions of the photometric center of the regions, in units of arcseconds. The coordinate system is centered on the nucleus of the galaxy \((\text{RA} = 09^h 55^m 35^s 25; \text{DEC} = 69^\circ 21' 50'' .9, \text{in J2000})\). The X-axis is along the E-W direction with positive values towards the east, and the Y-axis is along the N-S direction with positive values towards the north. Column 3 to Column 14 give the fluxes relative to the BATC08 filter (6075Å). Column 15 gives the flux in the BATC08 filter in units of \( 10^{-30} \text{ergs}^{-1}\text{cm}^{-2}\text{Hz}^{-1} \). For convenience in later discussions, we define the ‘central’ areas as regions with \(|\Delta RA| \leq 1'.0, |\Delta DEC| \leq 1'.9\), the ‘bulge’ region with \(1.0 < |\Delta RA| \leq 3'.4, 1.9 < |\Delta DEC| \leq 4'.0\) and the ‘disk’ region with \(3.4 < |\Delta RA| \leq 6'.2, 4'.0 < |\Delta DEC| < 8'.0\).

We show a black and white image of M81 in Figure 1. To display the features clearer, a “true-color” image of M81 is available in the electronic version, which is combined with the “blue” (3894Å), “green” (5785Å) and “red” (7010Å) filters. The filters selected here are free from any strong emission lines. From this image, we can see directly the stellar population difference in different areas of the spiral galaxy M81. In the following sections, we will analyze quantitatively the stellar populations in M81 with our 13 color data.

The bright HII regions consist of young clusters, and the evolutionary population synthesis methods used in this paper do not represent young clusters well. In addition, the central nucleus of M81 exhibits some of the same characteristics as classical Seyfert galaxies, has no evidence of stellar clusters or a population of hot young stars [Kaufman et al. 1996, Devereux et al. 1997, Davidge & Courteau 1999]. So we mask some bright HII regions and the central nucleus of M81 (shown as white spots in Fig. 4a, 5, 6, including the foreground stars) in this paper.

[2] The full Table 2 and color versions of Figs. 1, 4a, 5 and 6 are available electronically.

Note. — Rows 1-5, 6-10, 11-15 are for the central, bulge and disk areas respectively. The absolute flux (last column) is in units of $10^{-30}\text{ergs} \cdot \text{cm}^{-2} \cdot \text{Hz}^{-1}$. The full table for M81 is available electronically. The pixel values for the center of M81 is (300, 375).
Fig. 1.— “True-color” estimate of the M81 generated by using the BATC02 (3894 Å) filter image for blue, BATC07 (5785 Å) for green, and BATC10 (7010 Å) for red; the image is balanced by making the background old population orange and hot stars blue. The center (origin) of the image is located at $\alpha = 09^h 55^m 35^s.25, \delta = 69^\circ 21' 50'' .9$ (J2000.0). The image size is about 17’0 by 21’0. North is up and east is to the left. We refer to the region with $|\Delta RA| \leq 1'.0, |\Delta DEC| \leq 1'.9$ as the central region, the region with 1.0 < $|\Delta RA| \leq 3'.4, 1.9 < |\Delta DEC| \leq 4'.0$ as the bulge, and the region with 3'.4 < $|\Delta RA| \leq 6'.2, 4'.0 < |\Delta DEC| < 8'.0$ as the disk. A black and white image of Figure 1 be displayed in paper, the “true-color” image of Figure 1 is available in the electronic version.
3. DATABASES OF SIMPLE STELLAR POPULATIONS

A simple stellar populations (SSP) is defined as a single generation of coeval stars with fixed parameters such as metallicity, initial mass function, etc (Buzzoni 1997). In evolution synthesis models, they are modeled by a collection of stellar evolutionary tracks with different masses and initial chemical compositions, supplemented with a library of stellar spectra for stars at different evolutionary stages. Because SSPs are the basic building blocks of synthetic spectra of galaxies that can be used to infer the formation and subsequent evolution of the parent galaxies (Jablonka et al. 1996). In order to study the integrated properties of stellar population in M81, as the first step, we use the SSPs of Galaxy Isochrone Synthesis Spectra Evolution Library (Bruzual & Charlot 1996 hereafter GSSP). We study the SSPs as the first step for two reasons. First, they are simple and reasonably well understood, so it is important to see what one can learn using this simplest assumption, and then check whether more complex star formation history give qualitatively similar conclusions. This is a common approach often taken in the evolutionary population synthesis models for galaxies (Vazdekis et al. 1997, Mayya 1995). Second, although we assume each pixel is described by an SSP, we emphasize that the whole galaxy is not SSP; so our assumption is not as strong as it may seem. Nevertheless, this is a significant assumption. Fortunately, it appears the adoption of more complex star formation history does not change the results qualitatively; we return to this issue in §5.1.

3.1. Spectral Energy Distribution of GSSPs

The Bruzual & Charlot (1996) study has extended the Bruzual & Charlot (1993) evolutionary population synthesis models. The updated version provides the evolution of the spectrophotometric properties for a wide range of stellar metallicity. They are based on the stellar evolution tracks computed by Bressan et al. (1993), Fagotto et al. (1994), and by Girardi et al. (1996), who use the radiative opacities of Iglesias et al. (1992). This library includes tracks for stars with metallicities $Z = 0.0004, 0.004, 0.008, 0.02, 0.05$, and $0.1$, with the helium abundance given by $Y = 2.5Z + 0.23$ (The solar metallicity is $Z_\odot = 0.02$). The stellar spectra library are from Lejeune et al. (1997,1998) for all the metallicities listed above, which in turn consist of Kurucz (1995) spectra for the hotter stars (O-K), Bessell et al. (1991) and Fluks et al. (1994) spectra for M giants, and Allard & Hauschildt (1995) spectra for M dwarfs. The initial mass function is assumed to follow the Salpeter’s (1955) form, $dN/dM \propto M^{-2.35}$, with a lower cutoff $M_l = 0.1M_\odot$ and an upper cutoff $M_u = 125M_\odot$ (Sawicki & Yee 1998).

3.2. Integrated Colors of GSSPs

To determine the age, metallicity and interstellar medium reddening distribution for M81, we find the best match between the observed colors and the predictions of GSSP for each cell of M81. Since the
observational data are integrated luminosity, to make comparisons, we first convolve the SED of GSSP with BATC filter profiles to obtain the optical and near-infrared integrated luminosity. The integrated luminosity $L_{\lambda i}(t, Z)$ of the $i$th BATC filter can be calculated with

$$L_{\lambda i}(t, Z) = \frac{\int_{\lambda_{\text{min}(i)}}^{\lambda_{\text{max}(i)}} F_{\lambda}(t, Z) \varphi_i(\lambda) d\lambda}{\int_{\lambda_{\text{min}(i)}}^{\lambda_{\text{max}(i)}} \varphi_i(\lambda) d\lambda},$$

(1)

where the $F_{\lambda}(t, Z)$ is the spectral energy distribution of the GSSP of metallicity $Z$ at age $t$, $\varphi_i(\lambda)$ is the response functions of the BATC filter system, and $\lambda_{\text{min}(i)}$ and $\lambda_{\text{max}(i)}$ are respectively the maximum and the minimum effective wavelength of the $i$th filter ($i = 1, 2, \cdots, 13$).

The absolute luminosity can be obtained if we know the distance to a galaxy and the extinction along the line of sight. Since we do not know the exact distance to M81, in this paper, we shall work with the colors that are independent of the distance. We calculate the integrated colors of a GSSP relative to the BATC filter BATC08 ($\lambda = 6075$ Å):

$$C_{\lambda i}(t, Z) = L_{\lambda i}(t, Z)/L_{6075}(t, Z).$$

(2)

As a result, we obtain intermediate-band colors for 6 metallicities from $Z = 0.0004$ to $Z = 0.1$. In the panels of Fig. 2, we plot the colors as a function of age for GSSP with different metallicities. The following remarks can be made. (a) It is apparent that there is a uniform tendency for SSPs to become redder for all colors as the metallicity increases from $Z = 0.0004$ to $Z = 0.05$. The near-UV and optical colors show the same qualitative behavior as those at longer wavelengths. (b) There is a wide range in age (from 1 to 20 Gyr) in which the colors vary monotonically with time except for the highest metallicity $Z = 0.1$. Therefore, once we know the metallicity and interstellar reddening, we can use these colors to determine the age distribution of M81, provided that the stellar population is well modeled by SSPs. (c) For $Z = 0.1$, there is only a limited age range for the monotonic behavior in colors. One reason for this behavior is the appearance of AGB-manqué stars at $Z = 0.1$. These stars skip the AGB phase and directly go through a long-lived hot HB phase (Bruzual & Charlot 1996). There are very few, if any, examples of galactic stars with such a high metallicity. So our results are not affected by this peculiar high-metallicity case.

### 3.3. Color Indices of GSSPs

The observed colors are affected by interstellar reddening, which will of course complicate our interpretations (Ostlin et al. 1998). The interstellar reddening in the center region of M81 can be measured by its emission lines, but for the outer regions, the problem becomes very complex. If we suppose that the extinction law from 3800 Å to 10000 Å has no high frequency features, the spectral indices will not be affected much by the uncertainties in the extinction, so we can use the spectral indices to reduce the effect
Fig. 2.— Evolution of eight selected colors $C_{\lambda_i}$ (cf. eq. 3) for simple stellar population (SSP) models for different metallicities as predicted by the GISSEL96 library. Each line pattern represents a different metallicity, as indicated inside the frame. All the models shown are computed with a the Salpeter(1955) initial mass function with a lower cutoff of $0.1M_\odot$ and an upper cutoff of $125M_\odot$. 
of interstellar extinction.

Spectral indices are (by definition) constructed by means of a central band pass and two pseudo-continuum band-pass on either side of the central band. The continuum flux is interpolated between the middle-points of the pseudo-continuum band passes (Bressan et al. 1996, Worthey et al. 1997). Since we only observed M81 with intermediate-band filters, not a genuine one-dimensional spectrum, so we must use some pseudo-color indices to replace the conventional definitions. We define a color index $I_{\lambda_j}(t, Z)$ of a SSP by

$$I_{\lambda_j}(t, Z) = \frac{L_{\lambda_j}(t, Z)}{L_{\lambda_{j+1}}(t, Z)},$$

(3)

where $L_{\lambda_j}(t, Z)$ is the luminosity of a SSP with the metallicity $Z$ at age $t$ and wavelength $\lambda_j$, $L_{\lambda_{j+1}}(t, Z)$ is the luminosity in the $(j + 1)$th filter for the same SSP. The color indices can reduce the effect of reddening, especially in the wavelength region longer than 5000 Å.

Among all the BATC filter bands, we find that the color index centered at 8510 Å ($I_{8510}$) is much more sensitive to the metallicity than to the age; the center of this filter band is near the CaII triplets ($\lambda = 8498, 8542, 8662$ Å). The strength of CaII triplet depends on the effective temperature, surface gravity and the metallicity for late type stars (Zhou 1991).

In an old stellar system, the effect of metallicity on CaII triplet becomes prominent. In fact, we find that there is a very good relation between the flux ratio of $I_{8510} \equiv L_{8510}/L_{9170}$ and the metallicity for stellar populations older than 1 Gyr. We plot this relation in Figure 3. Similar relations are also found in many other observation and stellar population synthesis models.

The relation shown in Figure 3 is crucial for our metallicity determination and later studies, so it is important to check whether this is indeed a reliable method. An early study by Alloin & Bica (1989), based on the analysis of stars, star clusters and galaxy nuclei indicated a strong correlation of CaII triplet with the surface gravity, log $g$. However, further studies suggested that the CaII triplet strength depends not only on the surface gravity but also on the metallicity. A detailed analysis of the behavior of the CaII triplet feature as a function of stellar parameters was performed by Erdelyi-Mendes & Barbuy (1991), making use of a large grid of synthetic spectra. They concluded that CaII triplet has a weak dependence on the effective temperature, a modest dependence on surface gravity, but a quite important dependence on metallicity. They even suggested that the CaII triplet strength may vary exponentially with the metallicity. Moreover, these lines have been studied by Diaz et al. (1989), Mallik (1994) and Idiart et al. (1997). They have also suggested the CaII triplet strengths depend on the metallicity (Mayya 1997). So the relation between the $I_{8510}$ and metallicity seems to be reliable and can be used to determine the metallicities; our own investigation of GSSPs seems to be consistent with these recent studies.
Fig. 3.—a) Dependence of the pseudo color-index $I_{8510}$ with metallicity for the GISSEL96 SSP models. The line symbols are the same as in Fig. 2. The metallicities are labeled above each line. b) The correlation between the pseudo color-index $I_{8510}$ and metallicity, for five different ages ($T = 15, 10, 5, 3, 1$ Gyr). The solid line shows the best fit through the curves. The lower panel for the PSSPs, the upper panel for the GSSPs.
4. DISTRIBUTION OF METALLICITY, AGE AND REDDENING

In general, the SED of a stellar system depends on age, metallicity and reddening along the line of sight. The effects of age, metallicity and reddening are difficult to separate (e.g., Calzetti 1997, Origlia et al. 1999, Vazdekis et al. 1997). Older age, higher metallicity or larger reddening all lead to a redder SEDs of stellar systems in the optical (Molla et al. 1997, Bressan et al. 1996). In order to separate the effects of age, metallicity and interstellar reddening of M81, we first determine the metallicity by the color index $I_{8510}$, as discussed above, and then obtain the age and reddening by using GSSP model of known metallicity and a extinction law (see §4.2).

4.1. Metallicity distribution

As discussed in §3.3, there is a good correlation between the color index $I_{8510}$ and the metallicity. We will use the relation obtained from GSSP; this relation is similar for other stellar population synthesis models. We find that the correlation can be fit with a simple formula:

$$Z = (0.83 - 0.84 \times I_{8510})^2.$$  \hspace{1cm} (4)

This curve is shown in the upper panel of Figure 3. The scatter in Figure 3 is due to the difference in age. If the ages are younger than 1 Gyr, the scatter becomes larger. Figure 3 shows that for a stellar system of ages older than 0.5 Gyr, we can estimate the metallicity with an error less than the interval of metallicity given by GSSPs.

Using this method we obtained the metallicities for each part of M81 except for the nucleus and the Hα line emission region (we have masked them out, see §2.2). Figure 4a shows the resulting metallicity map of M81. Figure 4b shows the radial distribution of the metallicity, the curve is derived from the Fig. 4a by averaging over ellipses of widths 17" along the major axis. We used an inclination angle of $i = 59^\circ$ and a position angle of $PA = 157^\circ$ for the major axis of the galaxy.

To our surprise, we do not find, within our errors, any obvious metallicity gradient from the central region to the bulge and disk of M81. In most parts of M81, the mean metallicity is about 0.03 with variation $\lesssim 0.005$. These results are identical to past suggestions that early-type spirals may have relative high abundances and weak gradients. Taking into account of the age scatter, the true value of the metallicity is likely within a range between $Z = 0.02$ and $Z = 0.05$. From the metallicity map of M81, we can also clearly see that in some outer regions the metallicities are higher; most of these regions are located in spiral arms and around HII regions, where a younger stellar population is present.
Fig. 4a.— A map of the population metallicity in M81. Light gray corresponds to the low and dark gray to the high metallicity. Some bright HII regions, the central nucleus of M81 and most of foreground stars are masked, shown as white spots.
Fig. 4b.— The radial distribution of metallicity for M81, averaging over ellipses along the major axis (its position angle is taken to be 157°). The line is the regression line obtained by a polynomial fit. No obvious metallicity gradient exists from the central region to the bulge and disk of M81.
4.2. Age and reddening distribution

Since we model the stellar populations by SSPs, the observed colors for each cell are determined by two parameters: age, $t$, and dust reddening, $E(B-V)$. In this section, we will determine these parameters for M81 simultaneously by a least square method. The procedure is as follows. For given reddening and age (recall that the metallicity is known, see the previous subsection), we can obtain the predicted integrated colors by convolving the dust-free predictions from GSSP with the extinction curve given by Zombeck (1990). The best fit age and reddening values are found by minimizing the difference between the observed colors and the predicted values:

$$R^2(x, y, t, Z, E) = \sum_{i=1}^{12} \left[ C_{\lambda_i}^{\text{obs}}(x, y) - C_{\lambda_i}^{\text{ssp}}(t, Z, E) \right]^2,$$

where $C_{\lambda_i}^{\text{ssp}}(t, Z, E)$ represents integrated color in the $i$th filter of a SSP with age $t$, metallicity $Z$ and reddening correction $E$, and $C_{\lambda_i}^{\text{obs}}(x, y)$ is the observed integrated color at position $(x, y)$.

Figure 5 shows the age map for M81. It clearly indicates that the stellar population in the central regions is much older than that in the outer regions and the youngest components reside in the spiral arms of M81. There is a smooth age gradient from the center of the galaxy to the edge of the bulge. The age in the innermost central region (within 17") is older than $\gtrsim 15$ Gyr. The age at the more extended central region is about 9 Gyr. In the bulge edge area, the age is about 4 Gyr. In contrast, the stellar component in the disk area is much younger than that in the bulge region. The mean age in disk area is about 2.0 Gyr. We can see that the age in spiral arms is even younger than the inter-arm areas, about 1 Gyr.

Because the age obtained in the outer disk region is around 1 Gyr, the metallicity, which is determined by the color indices, might have large errors (see §4.1). The errors in turn will make the age determination uncertain. Therefore the age for disk can only be regarded as a rough estimation. However, the general trend in the age distribution should be reliable.

Figure 6 shows the reddening map for M81. From this figure, we find a large difference in reddening between the bulge and the disk. In the bulge, the reddening, $E(B-V)$, is in the range of 0.08 to 0.15. For regions where $E(B-V)$ is larger than 0.1, we found some spiral like cirrus. There is a very obvious high reddening lane around the nucleus with reddening equal to or higher than the disk area. The maximum of $E(B-V)$ in the lane reaches 0.25. This half-loop lane can be verified in the future with IR or CO line observations. In the disk area, the mean reddening of $E(B-V)$ is about 0.20. In the central regions, the mean reddening of $E(B-V)$ is very small. These results suggest that dust is largely absent in the central regions of M81. The dust seems to be distributed mainly along the inner part of spiral arms and around the nucleus. Color versions of Figs. 4-6 are available electronically.
Fig. 5.— A map of the population ages in M81. Light gray corresponds to the young and dark gray to the oldest zones. Same as in Fig. 4a, the white spots represent the masked regions, such as bright HII regions, the central nucleus of M81 and most of foreground stars.
Fig. 6.— The interstellar reddening map of M81, using the method described in the text.
5. DISCUSSION

The results we presented so far are based on the (strong) assumption that all stars in a small region form in an instantaneous burst and hence the stellar population of each cell can be modeled as SSPs. Unfortunately, the star formation rate history is an essential but very uncertain ingredient in the evolutionary population synthesis method since it can vary from galaxy to galaxy and from region to region inside a single galaxy as well. It is only for simplicity that we have adopted an instantaneous star formation history, clearly it is important to check whether the results are significantly changed if one varies the star formation history; we address this issue in §5.1. While there seems to be general agreement between the GISSEL96 SSPs models (which we used) with other similar ones (Charlot et al. 1996), there are some fine differences. In §5.2, we study how the results are changed if we adopt a different population synthesis model from the Padova group. In §5.3, we compare our results with earlier works.

5.1. Continuous Star Formation

We assume that stars are formed from the interstellar gas exponentially with a characteristic time-scale $\tau$, i.e., $\Psi(t) = \Psi_0 \exp^{-t/\tau}$. This model is often used to calculate the integrated colors of galaxies (Kennicutt 1998) and allows a more diverse star formation history. If $\tau \to \infty$ the model approximates constant star formation rate, while for $\tau \to 0$ it approximates an instantaneous burst (Abraham et al. 1999). It seems that spiral galaxies could be well fitted with $\tau$ of the order of several Gyr (Fioc et al. 1997).

Since we do not know the appropriate $\tau$ value for M81, we have explored the values $\tau = 0.1, 1, 3$ Gyr. We have calculated the age, metallicity and interstellar reddening distributions for each value of $\tau$. As the value of $\tau$ increases, the age ($t$) increases throughout M81, while the interstellar reddening decreases and the metallicity is little changed. Although the numerical values of these quantities do change in each point of M81, the two dimensional distributions of age, metallicity and interstellar reddening of M81 for different values of $\tau$ are similar to the ones shown in Figs. 4-6.

5.2. Comparison With Other SSP Models

There exist a number of SSP models that are synthesized with different approaches. It is important to check the sensitivity of our results to the SSP models adopted. The SSP models from the Padova group (hereafter, PSSPs) is suitable for the comparison, because they use a similar technique of “isochrone synthesis” to predict the spectral evolution of stellar populations. The PSSPs provide the basis for the population synthesis models (Bressan et al. 1994, see Bressan et al. 1996 for revisions and extensions). The PSSPs use a comprehensive set of stellar evolutionary tracks of the Padova group for a wide range of
initial chemical compositions from $Z = 0.0004$ to $Z = 0.1$ with $\Delta Y/\Delta Z = 2.5$. The initial masses of the evolutionary tracks cover the range of $0.6 - 120 M_\odot$, except for the set of metallicity $Z=0.1$, where the masses are from $0.6 - 9 M_\odot$. The initial mass function is the Salpeter (1955) law. More details can be found in Bressan et al. (1994), Silva (1995), and Tantalo et al. (1996). The main difference between GSSPs and PSSPs is the library of stellar spectra: the GSSPs use theoretical stellar spectra from Lejeune et al. (1997) while the PSSPs use theoretical stellar spectra from Kurucz (1992).

Using our method, we calculate the colors and color indices for each PSSP in the BATC filter system. Using similar procedures as for the GSSP (see §4), we obtained the metallicity, age and reddening distributions of M81. For PSSP, the metallicity map of M81 again has no obvious metallicity gradient, but the mean metallicity is somewhat higher, about 0.035. There is a smooth age gradient from the center of M81 to the edge of the bulge, except that the mean age in the disk area is lower than 1 Gyr. The interstellar reddening value from PSSP is obviously bigger than that from GSSP. In the bulge, the reddening value is in the range of 0.18 to 0.35. In the disk area, the mean reddening of E(B-V) is about 0.40. The reddening value in the central region amounts to 0.15. The distributions of metallicity, age and interstellar reddening are very similar to those found using GSSP.

5.3. Comparison with previous work

Numerous determinations of the amount of extinction in M81 have recently been obtained. Allen et al. (1997) compared the detailed distribution of HI, $H\alpha$, 150 nm Far-UV continuum emission in the spiral arms of M81. They found every reliable bright peak in the $H\alpha$ has a peak in the Far-UV, and concluded that the effects of extinction on the morphology are small on the spiral arms. Filippenko & Sargent (1988), based on the ratio of the narrow components of $H\alpha$ and $H\beta$, concluded that the central regions of M81 is reddened by $E(B-V)=0.094$ mag. These results are very similar to our results for internal reddening, that the mean reddening in the spiral arms and in the central regions of M81 are small. In addition, Kaufman et al. (1987, 1989), using the $H\alpha$ and radio continuum (Bash & Kaufman 1986) observations, have studied the distribution of extinction along the spiral arms in M81, and obtained a mean $A_v = 1.1 \pm 0.4$ mag for 42 giant HII regions with high surface brightness. Hill et al. (1992) used Near-UV, Far-UV and V-band images of M81 and cluster models to derive an $A_v = 1.5$ mag for the HII regions on the arms. These internal reddening values are larger than ours for spiral arms. It can be explained for two reasons. First, the internal reddening value of Kaufman et al. are derived from the giant HII regions of M81 with high surface brightness, but these bright HII regions are excluded in our study. So we have have used different regions for the internal reddening study, it is therefore not clear that they must agree. Second, the continuum regions are affected less by reddening than the emission line regions in a galaxy. The internal reddening value of Kaufman et al. is the reddening for emission line regions, but our results are from the continuum regions. The former
is significantly larger than the latter; this systematic difference has been seen in many other emission line galaxies (Kong & Cheng 1999; Calzetti 1997).

Perelmuter et al. (1995) have obtained spectra for 25 globular cluster in M81. Following the method of Brodie & Huchra (1990), based on the weighted mean of six indices, they measured these clusters’ metallicity. The mean metallicity was calculated both from the weighted mean of the individual metallicities, and directly from the cumulative spectrum of the 25 globulars. Both results yielded the same value, ⟨Fe/H⟩ = −1.48 ± 0.19 (Z = 0.033), which is identical to that derived by Brodie & Huchra (1991) using 8 clusters ((Fe/H) = −1.46 ± 0.31). No correlation has been observed between magnitude and metallicity of the globulars in the Milky Way and in M31. Thus the mean metallicity of the 25 globulars should be representative of the M81 system as a whole. These results agree with our results for the metallicity of M81 (Z ≈ 0.03) very well.

On the other hand, using the low-dispersion spectra of 10 HII regions in M81, Stauffer & Bothun (1984) estimated the oxygen abundances for those HII regions from the observed emission lines. They derived a mean abundance near solar and a weak abundance gradient in M81. Using the empirical calibration method and the photoionization models, Garnett & Shields (1987) have analyzed the metallicity abundance and abundance gradients for 18 HII regions in the galaxy M81. The major result of this study is the presence of order-of-magnitude gradient in the oxygen abundance across the disk of M81. These results differ from ours. However, the differences can be readily explained. First, as for the internal reddening, the previous results are derived from the bright HII regions of M81, the abundance gradient is therefore for these HII regions. But our result come from the whole galaxy except these bright HII regions. So it is not clear that they should have the same behaviors in metallicity. Another caveat to the previous results is that the Pager et al. (1980) abundance calibration (which was used in Stauffer & Bothun 1984, Garnett & Shields 1987) is not expected to be exact.

At last, we must emphasize that although the method we used in this paper can be used to constrain the variation of metallicity, population age, and reddening across M81 are for the central region, the bulge, and the disk minus the spiral arms, it may not be suited to study the property of the spiral arms. There are two main reasons. First, there are hundreds of HII regions on the spiral arms, and, the evolutionary population synthesis methods that we used in this paper are not well represented very young clusters. Second, the signal-to-noise ratio decreases from the center to the edge of the galaxy, we have smoothed the images with a boxcar filter (See §2.2). For the outer disk regions, such as the spiral arms, the smoothing tends to blend the hundreds of HII regions with their surroundings. We will study these bright HII regions at the spiral arms of M81 in more detail in a subsequent paper when we have better data, using the evolutionary population synthesis method, and show how well it can work for young clusters.
6. Conclusions

In this paper, we have, for the first time, obtained a two-dimensional SED of M81 in 13 intermediate colors with the BAO 60/90 cm Schmidt telescope. Below, we summarize our main conclusions.

- Using the new extensive grid of GSSPs covering a wide range of metallicity and age, we calculated the colors and color indices for 13 colors in BATC intermediate-band filter system. We find that some of them can be used to break the age and metallicity degeneracy, which enables us to obtain two-dimensional maps of metallicity, interstellar reddening and age of M81.

- From the two dimensional metallicity distribution of M81, we find no obvious metallicity gradient from the central regions to the outer disk. In most part of M81, the mean metallicity is about 0.03 with variation $\lesssim 0.005$. Some regions in M81, however, have higher metallicity; they are mostly located in the spiral arms and around HII regions, where the younger component resides.

- From the two dimensional age distribution in M81, we find that the mean ages of the stellar populations in the central regions are older than those in the outer regions, which suggests that star formations in the central regions occurred earlier than the outer regions.

- We find a strong difference in reddening between the bulge region and the disk region. In the bulge area, the reddening, $E(B-V)$, is in the range of 0.08 to 0.15. The mean reddening in the disk area is higher, about 0.2. There are some high reddening spiral-like cirrus in the bulge.

- In order to understand how sensitive our method is to different assumptions about star formation history and different stellar population synthesis models, we have studied an exponential star formation history and compared the results obtained with GSSP and PSSP. We find that although the precise values of age, metallicity and interstellar reddening are different, the general trend of in the metallicity, age and reddening distributions is similar.

- Finally, we have compared the internal reddening and metallicity maps of M81 with previous studies. We find that the agreements are generally good. In addition, we find that the properties for the bright HII regions and other parts may be different.

The results of M81 presented here illustrate that our method and observational data provide an efficient way to study the distribution of metallicity, age and interstellar reddening for nearby face-on galaxies. Similar data have already been collected for similar galaxies M13, NGC589 and NGC5055. The analysis results of these galaxies will be published in a forthcoming paper.
We are indebted to Dr. Michele Kaufman for a critical and helpful referee’s report that improved the paper. We would like to thank A. Bressan, D. Burstein, and G. Worthey for useful discussion and suggestion. We are grateful to the Padova group for providing us with a set of theoretical isochrones and SSPs. We also thank G. Bruzual and S. Charlot for sending us their latest calculations of SSPs and for explanations of their code. The BATC Survey is supported by the Chinese Academy of Sciences (CAS), the Chinese National Natural Science Foundation (CNNSF) and the Chinese State Committee of Sciences and Technology (CSCST). Fuzhen Cheng also thanks Chinese National Pandeng Project for financial support. The project is also supported in part by the U.S. National Science Foundation (NSF Grant INT-93-01805), and by Arizona State University, the University of Arizona and Western Connecticut State University.
