Abstract

Background: The beneficial effects of epidural analgesia (EDA) in terms of pain control and postoperative convalescence are widely known and led to a frequent use for patients who underwent living donor kidney nephrectomy. The objective of this study was to determine whether general anesthesia (GA) plus EDA compared to GA only, administered for living donor nephrectomy has effects on postoperative graft function in recipients.

Methods: In this monocentric, retrospective cohort analysis we analyzed the closed files of all consecutive donor-recipient pairs who underwent living donor kidney transplantations from 2008 to 2017. The outcome variable was delayed graft function (DGF), defined as at least one hemodialysis within seven days postoperatively, once hyperacute rejection, vascular or urinary tract complications were ruled out. Statistical analyses of continuous variables were calculated using the two-tail Student's t test and Fisher exact test for categorical variables with a significance level of p<0.05, respectively.

Results: The study enclosed 291 consecutive living donor kidney transplantations. 99 kidney donors received epidural analgesia whereas 192 denied epidural analgesia. The groups showed balanced pretransplantational characteristics and comparable donors' and recipients' risk factors. 9 out of all 291 recipients needed renal replacement therapy (RRT) during the first 7 days due to delayed graft function; all of these donors received no EDA. The observed rate of DGF in recipients whose kidney donors received epidural analgesia was significantly lower (0% vs. 4.6%; p<0.031).

Conclusions: In our cohort we observed a significantly lower rate of DGF when epidural analgesia for donor nephrectomy was administered. Due to restrictions of the study design this observation needs further confirmation by prospective studies.

Key words: Kidney transplantation, delayed graft function, epidural analgesia, donor nephrectomy

Background

Living kidney transplantation showed superior results compared with deceased donor kidney transplantation in terms of graft survival, accessibility, waiting time and cost containment for public health services\(^1\)\(^-\)\(^3\). For patients undergoing surgical procedures for another one's benefit, it is important to minimize perioperative risk and inconvenience. Furthermore it is the healthcare providers' duty to maximize the beneficial impact of the donation for the recipient.

In numerous studies major outcome benefits like mortality of EDA could neither be confirmed nor denied\(^4\),\(^5\). However, the beneficial effects of EDA in terms of intra- and postoperative pain control, intestinal motility, early mobilization and duration of ICU-hospitalization are widely known and find broad acceptance\(^6\)\(^-\)\(^9\). Therefore it is not surprising, that continuous EDA is a mandatory part of many surgical fast track programs\(^1\(^0\)\(^-\)\(^1\(^2\). In order to provide these advantages also for kidney donors and to increase
their convalescence and speed up their reintegration in daily life, we offered EDA to patients for donor nephrectomy if contraindications were ruled out and patients gave their informed consent. The primary intent of providing perioperative EDA for donor nephrectomy are the beneficial effects for the donor. These EDA effects are mostly mediated by perioperative sympathicolysis which probably may have effects on the kidney intended for transplantation. Potential effects on graft function of kidneys explanted from donors with EDA have not been reported yet. Therefore the aim of this hypothesis generating study was to determine whether GA plus EDA compared to GA only, administered for living donor nephrectomy is associated with beneficial effects on postoperative graft function after transplantation.

**Methods**

This retrospective cohort study was approved by the local Institutional Review Board, University of Freiburg, Germany (approval number EK 555/17). The study was conducted at the Department of Anesthesiology and Critical Care and the Department of General and Visceral Surgery, Medical Center - University of Freiburg, Faculty of Medicine - University of Freiburg Germany. The study was planned and designed in accordance with the initiative for Strengthening the Reporting of Observational Studies in Epidemiology (STROBE), using the suggested checklist for epidemiological cohort studies. The study was initiated and designed in March 2018; the retrospective data collection was conducted in June 2018. The onset of data collection is analogous to the existence of an electronic patient data management system on ICU which enabled data acquisition. As we enclosed only closed les and the data collection started in June 2018, cases after December 31st 2017 were not enclosed. The study cohort consists of all consecutive living donor kidney transplantations between October 2008 and December 2017 which determines the sample size. A priori sample size calculation is not applicable in this fully retrospective and observational study design. Figure 1 shows the protocol of data collection and statistical processing.

Recipient and donor evaluation were based on a check-up examination which lead to confirmation of donor suitability. Ahead of transplantation all donor-recipient pairs were evaluated by an ethics committee of the District Medical Association Suedbaden. A positive vote of this ethics committee was mandatory for transplantation.

Surgical procedure was standardized to a maximum as only two different surgeons contributed to the transplantations in this cohort. The donor nephrectomy was performed in supine position over an open anterior extraperitoneal minimal incision laparotomy. Transplantations were performed in the established technique, to the right iliac fossa of the recipient.

Decision on epidural analgesia was based on the patients’ preference. All patients that received epidural analgesia gave their informed consent on that procedure. Epidural analgesia was performed directly preoperatively according a specific departmental standard operating procedure: Epidural catheter was placed between the 7th and the 11th thoracic intervertebral space, followed by an application of 25 mg sufentanil and 10 ml ropivacaine 0.2 %. After the initial dose a continuous epidural application of 45 ml
ropivacaine 0.2 % mixed with 25 mg sufentanil (= ropivacaine 0.18 % and sufentanil 0.5 mg/ml) with a
infusion rate of 8 ml/h during the surgery was established. Anesthesia procedures for donor nephrectomy
with and without epidural analgesia followed corresponding standard operating procedures (SOP).
Postoperatively all donors were transferred to a transplantation ICU. Patients, who received epidural
analgesia, were visited daily by the acute pain service of our department. Epidural catheters were
removed between the second and the fifth postoperative day by the acute pain service.

Anesthesia for Transplantation was performed without epidural analgesia for the recipient and followed a
departmental SOP which was established and revised where necessary in close collaboration between
the responsible surgeons and anesthetists. The SOP addresses the need for 250 mg Prednisolone and 10
g Mannitol ahead of reperfusion. With the onset of reperfusion of the transplant kidney 125 mg
Furosemide were administered. Intraoperative fluid and catecholamine management was performed by
the attending anesthetist referring to the SOP.

Renal replacement therapy (RRT) was initiated when patients were threatened by volume overload or
increased serum potassium levels. Delayed graft function was defined as any renal replacement therapy
in the first postoperative week, once hyperacute rejection, vascular or urinary tract complications were
ruled out \(^{14-16}\).

Statistics:

The data was collected in a MS Excel™ (Microsoft, Redmond, USA) datasheet. Further statistical
processing was performed using SPSS™ (IBM, Armonk, USA). Statistical analyses of continuous variables
were calculated using the two-tail Student’s t test and Fisher Exact test for categorical variables with a
significance level of p<0.05, respectively.

Results

The study enclosed 291 consecutive living donor kidney transplantations between October 2008 and
December 2017. 99 kidney donors received epidural analgesia whereas 192 denied epidural analgesia. All
recipients underwent kidney transplantation due to end stage renal disease. No mortality was reported in
either group. In the EDA group no epidural catheter associated complications were found.

The perioperative characteristics are shown in table 1. The two study groups showed no significant
differences in several donors´ risk factors except a significantly shorter nephrectomy time (135 vs. 144
min, p<0.003). The intraoperative fluid consumption (1813 vs. 2191 ml; p=0.053) and maximum dose of
vasopressor (0.03 vs. 0.06 mg/kg/min; p=0.300) showed no statistically significant difference. None of
the recipients´ pre- and intratransplantation data showed a significant difference (table 1). After
transplantation, 14 out of all 291 recipients needed renal replacement therapy during the first 7 days after
transplantation, but only 9 cases because of delayed graft function. The other 5 recipients suffered from
humoral rejection, thrombosis of the iliac vessel or bleeding complications with the need of a surgical
revision (table 2). All kidney donors to these 9 recipients received GA without epidural analgesia. The
incidence of DGF was significantly higher in recipients whose donors did not receive epidural analgesia (4.6% vs. 0%; p<0.031) (figure 2). In line with this finding the serum creatinine level as well as the maximum serum potassium level within 7 days were significantly lower in the recipients whose donors received EDA (2.17 vs. 2.04 mg/dl, p<0.036; 5.15 vs. 5.11 mmol/l, p<0.001).

Discussion

The benefits of EDA regarding pain control, ICU stay, intestinal motility and early mobilization are frequently reported 17–22. The beneficial effects of EDA in terms of pain control and return to normal daily activities specifically for kidney donors have also been reported in the past 23,24. This retrospective cohort study of 291 living donor kidney transplantations compared 99 cases whose donors received EDA with 192 cases that received GA only, with regard to DGF in the recipients. The main result is that DGF is significantly more frequent in patients whose kidney donors did not receive EDA. The incidence of DGF in cohorts of living kidney transplantations varies from 4 to 10% and increases morbidity, healthcare costs, hospitalization times and complicates post-transplantation care 25–28. DGF predisposes for chronic rejection, chronic allograft nephropathy and seems to be causal for increased rates of graft failure and mortality 29,30.

In line with the significantly lower rate of DGF in EDA group, we found that serum creatinine level, as well as the maximum serum potassium level within 7 days, were significantly lower in the EDA group. Although these findings are statistically significant, their measured levels and differences in numbers are clinically questionable. Even when looking at the decline of the serum creatinine levels over the first two days postoperatively there can be found no significant or clinically relevant difference. The recipients of the no-EDA group start at a slightly higher level of serum creatinine which should be taken in account. Further baseline characteristics of donors and recipients showed no statistically significant difference or clinically relevant imbalance between the donors and recipients of both groups. An increased intraoperative fluid and vasopressor consumption in the EDA group could be associated with the EDA mediated inhibition of the sympa-tho-adrenal response with consecutive vasodilatation. However, neither intraoperative fluid nor vasopressor consumption showed a statistically significant difference in our study.

The standard surgical technique for donor nephrectomy in our institution is an open anterior extraperitoneal minimal incision laparotomy. Open surgical technique for donor nephrectomy is associated with inferior cosmetic result, longer hospitalization and more intra- and postoperative pain with consecutively increased need for pain medication 31,32. However, the open surgical approach showed superior results in terms of warm ischemia period, surgical costs, length of operation, intraperitoneal complications, recovery of graft function, recipient anastomosis difficulties and incidence of acute tubulus necrosis 33–35. It is reported that up to 25% of the living kidney donors after open surgical technique nephrectomy suffer from chronification of postoperative pain 36. A reduction of somatic pain within the first six postoperative weeks is associated with improved mental health of kidney donors 32.
These findings underline the need for EDA from the donors’ perspective. The described clinical benefits of EDA for the donor might lose their relevance and have to be reconsidered if the surgical approach in our institution changes to laparoscopic technique.

The reasons why kidney grafts fail to function immediately after transplantation when acute rejection, urological or vascular reasons are ruled out are associated with the transplanted kidney. DGF is modulated and caused by complex mechanisms of hypoxic and ischemic injuries and insufficient repair mechanisms. These cascades seem to be induced by the operative trauma and the corresponding physiological stress response during donor nephrectomy. It is known that surgical procedures and the physiological stress response are associated with intra- and postoperative hypercoagulability which results in postoperative thromboembolic and vaso-occlusive events. Increased levels of tissue factor, tissue plasminogen activator, plasminogen activator inhibitor-1, and von Willebrand factor which all contribute to hypercoagulability are reported to be found proximately after surgical stimulus. Due to inhibition of nociceptive and non-nociceptive pathways of sympathetic innervation of the adrenal glands, EDA with local anesthetics leads to a perioperative sympathicolysis. It is also reported that EDA modulates postoperative hypercoagulability by normalizing antithrombin III-activity and decreasing of platelet aggregation. This could be one of the reasons that we found a significantly increased rate of DGF in the group of patients who refused perioperative EDA.

The present study has several severe limitations.

First, the retrospective and non-randomized design implies that a study protocol which addresses randomization on who receives EDA is missing. It is speculative why patients opted for or against EDA, possibly the way whether EDA was offered by the visiting anesthesiologist or rather recommended plays an important role. Perhaps patients who opted for EDA were more trusting of their physicians and therefore had less anxiety or stress levels which may have influenced DGF of their donated kidney. RRT was initiated by visiting nephrology specialists and the request of the attending ICU physician when patients were threatened by volume overload or increased serum potassium levels. We were fully aware that living donor kidney transplantation is a highly complex procedure. The outcome quality is affected by various confounding variables for which we have not adjusted in our study due to the limited number of cases with DGF.

There are also several slightly different definitions on delayed graft function in literature. In our study DGF was defined as any renal replacement therapy in the first postoperative week, when hyperacute rejection, vascular and urinary tract complications were ruled out. More than 22 different definitions of DGF are described, the most common definition refers to any RRT within the first posttransplantational week. Due to the manageable size of our cohort we could screen every case of RRT for the underlying reasons. Knowing these reasons leading to RRT for every patient, we decided to choose a more specific definition of delayed graft function. Beyond the discussion about the definition, we have to state, that in the EDA group none of the patients who received RRT showed graft associated reasons leading to RRT. In no case of the EDA group, graft perfusion deficits or insufficient otherwise unexplainable graft dysfunction led to
RRT. Finally, we can report of an association between EDA for donor nephrectomy and a lower rate of DGF in our study. However, we were fully aware that correlation does not proof causality. Especially in such a multifactorial context like living kidney transplantations, larger numbers of prospectively randomized assigned patients are needed to provide stronger evidence.

**Conclusions**

In this retrospective cohort study, we found an association between epidural analgesia for living kidney donors and significantly less delayed graft function in the corresponding kidney recipients. These results favor not only the beneficial analgesic effect of epidural analgesia for donors but also shows significant beneficial effects for kidney recipients. As our study has relevant shortcoming in terms of study design, number of index cases and adjustment of confounding variables, our findings have to be confirmed by prospective randomized trials.

**Abbreviations**

DGF – delayed graft function  
EDA – epidural analgesia  
GA – general anesthesia  
RRT – renal replacement therapy  
SOP – standard operating procedure

| Recipient BMI [kg/m²]    | 24.8 ± 3.9           | 25.6 ± 4.2      | 0.168        |
| Recipient male sex [n/(%)] | 121 (62%)          | 61 (62%)        | 0.899        |
| Recipient age [years]    | 44 ± 13              | 47 ± 13         | 0.853        |
| Recipient rest diuresis [ml] | 1098 ± 907         | 1134 ± 858      | 0.062        |
| Recipient preoperative creatinine [mg/dl] | 8.0 ± 2.8           | 7.6 ± 2.8       | 0.744        |
| Duration of transplantation [min] | 161 ± 55           | 145 ± 41        | 0.129        |
| Warm ischemic period [min] | 29 ± 9              | 26 ± 7          | 0.138        |
| MAP for anastomosis [mmHg] | 93 ± 11             | 88 ± 16         | 0.165        |
| Fluid intake during transplantation [ml] | 2782 ± 1366       | 3477 ± 1233     | 0.559        |
| **Posttransplantation data** |                      |                 |              |
| Diuresis first hour [ml] | 425 ± 430           | 383 ± 390       | 0.358        |
| Diuresis 24 hours [ml]   | 9947 ± 5313         | 10871 ± 6419    | 0.062        |
| Recipient creatinine 12-24 hours postoperative [mg/dl] | 4.37 ± 2.2         | 4.09 ± 1.8      | 0.189        |
| Recipient creatinine 36-48 hours postoperative [mg/dl] | 3.15 ± 2.1         | 3.04 ± 1.7      | 0.404        |
| Recipient creatinine 7 days postoperative [mg/dl] | 2.17 ± 1.6         | 2.04 ± 1.1      | **0.036**    |
| Max. recipient serum potassium level within 7d | 5.15 ± 0.6         | 5.11 ± 0.4      | **0.001**    |
| Renal replacement therapy first postoperative week [n/(%)] | 11 (6%)            | 3 (3%)          | 0.312        |
| Delayed graft function [n/(%)] | 9 (4.6%)           | 0 (0%)          | **0.031**    |
| Case Number | EDA | Underlying reason leading to RRT within 7 days | DGF |
|-------------|-----|---------------------------------------------|-----|
| 507         | no  | graft perfusion deficit                      | yes |
| 581         | no  | insufficient graft function, later sepsis    | yes |
| 588         | no  | critical potassium levels, good graft function later on | yes |
| 624         | no  | acute tubules necrosis                       | yes |
| 666         | yes | humoral rejection                            | no  |
| 692         | no  | bleeding complication, needed operative revision | no |
| 701         | no  | insufficient graft function                  | yes |
| 829         | no  | humoral rejection                            | no  |
| 859         | no  | graft perfusion deficit                      | yes |
| 888         | no  | insufficient graft function, critical potassium levels | yes |
| 935         | no  | insufficient graft function                  | yes |
| 1017        | no  | insufficient graft function                  | yes |
| 1023        | yes | humoral rejection                            | no  |
| 1089        | yes | thrombosis of recipients iliac vessel        | no  |

**Figures**
