Modulated coupled nanowires for ultrashort pulses

Alexander S. Solntsev and Andrey A. Sukhorukov

We predict analytically and confirm with numerical simulations that inter-mode dispersion in nanowire waveguide arrays can be tailored through periodic waveguide bending, facilitating flexible spatio-temporal reshaping without break-up of femtosecond pulses. This approach allows simultaneous and independent control of temporal dispersion and spatial diffraction that are often strongly connected in nanophotonic structures.

High-index-contrast nanowires offer unique advantages for manipulation of optical pulses in compact photonic circuits, providing high field confinement and enabling precise dispersion engineering [1, 2]. In particular optical chips based on silicon sub-wavelength waveguides allow for efficient frequency conversion [3, 4], all-optical pulse control [5] and all-optical switching [6]. Furthermore, couplers [7] and arrays of coupled nanowire waveguides [8, 9] open possibilities for efficient spatio-temporal shaping of optical pulses. In order to harness these opportunities, it is essential to develop approaches to simultaneously and independently control temporal and spatial dispersion, as these characteristics can be strongly connected in nanophotonic structures. This connectivity can lead to difficulties designing a waveguide array supporting propagation of ultrashort pulses, since pulses either disperse due to strong temporal dispersion or break-up due to strong spatial diffraction [9].

One possible approach to achieve required spatio-temporal dispersion is to carefully design waveguide array geometry and use complex photonic crystal structures [10]. That is however a very complicated method. Another way to tailor dispersion is by introducing periodic waveguide bending [11, 13]. This approach allows relatively simple fabrication and offers substantial design flexibility. Periodic waveguide bending was introduced as an effective tool for polychromatic diffraction management [11, 13, 14], however it has only been studied in the context of continuous light illumination and conventional micro-scale waveguides. In this work, we develop an approach to simultaneously control spatial and temporal dispersion and demonstrate through numerical simulations the application of this concept to the suppression of ultrashort pulse distortion and break-up in nano-waveguide arrays.

Ultrashort pulses have a broad spectrum encompassing a large range of frequencies ω, therefore temporal dispersion characterized by a propagation constant βs(ω) has a significant influence on the pulse dynamics. In waveguide arrays pulses can also switch between different waveguides. One of the most important parameters characterizing waveguide arrays is a coupling coefficient Cs(ω), which determines the rate at which light couples between the neighboring waveguides and thus regulates the spatial dispersion. The coupling coefficient for straight lossless waveguides is real: Cs(ω) = Re[Cs(ω)].

It was shown previously [13] that bending the waveguides affects the coupling by introducing an additional phase shift. If all waveguides in an array have the same bending profile x0(z), where x0 is a transverse coordinate of the waveguide center and z is the propagation direction, then the complex electric field amplitude En in n-th waveguide of the array satisfies the following coupled-mode equations [13]:

\[
\begin{align*}
    i\partial_z & E_n(z, ω) + β_s(ω) E_n(z, ω) = \\
    & - C_s(ω) \exp \left[ m_0 d_w x_0(z) ω/c \right] E_{n-1}(z, ω) \\
    & - C_s(ω) \exp \left[ -m_0 d_w x_0(z) ω/c \right] E_{n+1}(z, ω).
\end{align*}
\]

Here \( m_0 \) is an effective refractive index, \( ω = 2πc/λ \) is the angular frequency, \( λ \) is a light wavelength in vacuum, and \( d_w \) is the distance between the coupled waveguides.

We extend this method to consider the dynamics of ultrashort pulses and study its applicability to nanophotonic structures. In low-index waveguide arrays both the propagation constant of individual waveguides and the coefficient characterizing coupling between the neighboring waveguides are mildly dispersive. In contrast, in nanowire high-index waveguides the dispersion can be much stronger, and also small changes of waveguide cross-section dramatically affect both temporal dispersion and spatial diffraction [9].

To investigate the pulse dynamics in the coupled nanowires we combine the approaches previously developed for the description of nanowire arrays [9] and curved conventional waveguide arrays [11, 14]. We derive the following system of equations by applying to Eq. [1] the Fourier transform \( \hat{E}_n(t) = \int dω\hat{E}_n(z, ω) \exp(-iωt) \), where \( t \) is time, and perform a Taylor expansion of coupling and propagation coefficients:

\[
\begin{align*}
    i\partial_z & \hat{E}_n(t) + \hat{β}\hat{E}_n(t) = \\
    & - \hat{C}(z) \hat{E}_{n-1}(t, z) - \hat{C}^*(z) \hat{E}_{n+1}(t, z).
\end{align*}
\]

Here \( \hat{β} \) determines the temporal dispersion in a waveguide, and \( \hat{C} \) characterizes the coupling between the neigh-
The corresponding Taylor expansion coefficients are:
\[
\beta_m = (\frac{\partial}{\partial \omega})^m \beta_s(\omega)|_{\omega=\omega_0},
\]
\[
c_m(z) = (\frac{\partial}{\partial \omega})^m [C_s(\omega) \exp (\sum_{n=0}^{m} \hat{C}_n(z) \omega/c)]|_{\omega=\omega_0},
\]
where \(\omega_0\) is the central pulse frequency. Note that the dispersion coefficients \(\beta_m\) do not depend on the coupling. On the other hand, the coupling coefficients \(c_m\) depend non-trivially on the propagation distance \(z\) through an interplay between the dispersion of coupling between the straight waveguides \(\beta_s\) and the bending profile \(x_0(z)\) induced dispersion.

It was shown \[13\] that for polychromatic light propagation in periodically curved waveguide arrays, after the full bending period the beam diffraction is the same as in a straight array with the effective coupling coefficient. We check that the same approach can be applied to the pulse propagation when \(x_0(z) \equiv x_0(z + L_b)\) and \(L_b\) is a modulation period, and the effective coupling is:
\[
C_{\text{eff}}(\omega) = C_s(\omega)L_b^{-1} \int_0^{L_b} \cos[n_0 d_w x_0(z) \omega/c] dz.
\]
Below we show that a special combination of the modulation parameters allows us to suppress the dispersion of the effective coupling coefficient and accordingly avoid the pulse distortion.

We investigate the influence of the periodic waveguide bending on the pulse reshaping, and consider a representative example of a cosine profile with the amplitude \(A\) and period \(L_b\):
\[
x_0(z) = A \cos(2\pi z/L_b).
\]
To demonstrate our approach, we consider coupled Si nanowire waveguides and use COMSOL RF module to calculate the dispersion in straight coupled waveguides. The dimensions of the wires are as follows. The wires are 220 nm high and 330 nm wide, placed on a silica slab. There is a 100 nm high etching mask with refractive index 1.35 on top of wires. Otherwise the wires are surrounded by air. We choose these parameters to obtain nearly zero group velocity dispersion \(\beta_2 \approx 0\) in the proximity of \(\lambda_0 = 1.5 \mu m\) wavelength for a single nanowire, as this would minimize the pulse distortion. We however emphasize that even in this regime, a pulse can exhibit distortion due to the dispersion of coupling between the nanowires in an array \[9\].

To determine the coupling strength between the neighboring waveguides, we follow the approach of Ref. \[9\] and analyze a two-waveguide coupler with wire-to-wire separation of 330 nm. We calculate the propagation constants for symmetric and antisymmetric supermodes of the coupler \(\beta_{\text{sym}}(\omega)\) and \(\beta_{\text{asym}}(\omega)\), respectively. The propagation constant for a single waveguide can be well approximated by the average of the symmetric and antisymmetric supermode propagation constants, \(\beta_s(\omega) \approx \frac{[\beta_{\text{sym}}(\omega) + \beta_{\text{asym}}(\omega)]}{2}\), while the difference defines the coupling coefficient \(C_s(\omega) = \frac{[\beta_{\text{sym}}(\omega) - \beta_{\text{asym}}(\omega)]}{2}\). The coefficients of the Taylor expansion of the propagation constant are found as \(\beta_0 = 7.85 \mu m^{-1}, \beta_1 = 17 fs\mu m^{-1}, \beta_2 = 1.4 fs^2\mu m^{-1}\). Accordingly, we find that the group
in agreement with the previous study [9]. These pulses (a,c) and into two pulses in the central waveguide (b), split into three separate pulses in the edge waveguides without significant distortions. Then the pulse starts to left (a) to the central (b) and then to right (c) nanowire (c) demonstrate that initially the pulse couples from the left nanowire of the straight waveguide array. Figs. 2(a-c) show the pulse propagation in straight waveguides [see Fig. 1(b)], which could lead to temporal reshaping of short pulses during propagation. The Taylor expansion of the coupling coefficient for straight waveguides is 

\[ \lambda_0 = 96 \text{ mm} \]

which reveals strong linear dispersion and small quadratic dispersion in the wavelength range between 1.46 \( \mu \text{m} \) and 1.54 \( \mu \text{m} \). The coupled waveguides support three supermodes, which characteristic spatial profiles are shown in Fig. 1(c). We calculate the dependence of the supermode propagation constants on the wavelength, see Fig. 1(c). These dependencies have different slopes corresponding to different supermode velocities. We show below that this leads to pulse splitting, which can be suppressed via periodic waveguide bending.

Next we consider an array of three coupled nanowires with all parameters as noted before, see Fig. 3(a). We use a three-waveguide system for all the following calculations, since it allows us to fully demonstrate the pulse control method proposed in this work. In agreement with predictions of Ref. [9], we notice that the variations of the coupling coefficient for such waveguide arrays are significant across a relatively narrow spectrum [see Fig. 1(b)], which could lead to temporal reshaping of short pulses during propagation. The Taylor expansion of the coupling coefficient for straight waveguides is 

\[ c_0 = 69.7 \text{ mm}^{-1}, \ c_1 = -0.71 \text{ fs } \mu \text{m}^{-1}, \ c_2 = 3.6 \text{ fs}^2 \mu \text{m}^{-1} \]

which reveals strong linear dispersion and small quadratic dispersion in the wavelength range between 1.46 \( \mu \text{m} \) and 1.54 \( \mu \text{m} \). The coupled waveguides support three supermodes, which characteristic spatial profiles are shown in Fig. 1(c). We calculate the dependence of the supermode propagation constants on the wavelength, see Fig. 1(c). These dependencies have different slopes corresponding to different supermode velocities. We show below that this leads to pulse splitting, which can be suppressed via periodic waveguide bending.

First we analyze the pulse dynamics in straight waveguides with length \( L = 20L_C = 315 \mu \text{m} \), where \( L_C = 15.75 \mu \text{m} \) is the length required for full coupling from one waveguide to another at the wavelength \( \lambda_0 \). As an input, we consider a single 100 fs long transform-limited Gaussian pulse with the central wavelength \( \lambda_0 \) coupled to the left nanowire of the straight waveguide array. Figs. 2(a-c) demonstrate that initially the pulse couples from the left (a) to the central (b) and then to right (c) nanowire without significant distortions. Then the pulse starts to split into three separate pulses in the edge waveguides (a,c) and into two pulses in the central waveguide (b), in agreement with the previous study [9]. These pulses propagate with different group velocities, which correspond to three different supermode velocities supported in the structure [see Fig. 1(c)]. Such behavior demonstrates that although the single nanowire propagation dispersion can be engineered, spatial diffraction in arrays of nanowires is still strongly limited by the coupling dispersion. Moreover the propagation dispersion and the coupling dispersion in nanowire waveguide arrays are interconnected, and therefore an approach allowing for the independent control of these characteristics would offer essential benefits for various applications.

Next, we investigate the influence of the periodic waveguide bending on the pulse reshaping. We choose a bending profile according to Eq. (7). We vary the bending amplitude \( A \) and search for the minima of the coupling dispersion \( \partial C_{\text{eff}}/\partial \omega \) in the vicinity of \( \lambda_0 \). We choose the bending period \( L_b = L_C = 15.75 \mu \text{m} \), as it allows us to consider nanowires with smaller curvature for the purposes of easier potential fabrication and reduction of propagation losses. As we show below, one can choose a bending profile that simultaneously allows for a strong coupling dispersion control and does not introduce bending propagation losses.

We calculate the effective coupling coefficient \( C_{\text{eff}} \) using Eq. (5). We choose the value of \( A = A_{\text{min}} \) corresponding to the first minimum of \( \partial C_{\text{eff}}/\partial \omega \), and accordingly the smallest suitable bending curvature. The optimal bending amplitude is found to be equal to \( A_{\text{min}} = 1.3 \mu \text{m} \). The bending losses for the corresponding curvature value should be practically absent according to the previous studies of bent nanowire waveguides [15]. The resulting effective coupling coefficient \( C_{\text{eff}} \) shown in Fig. 3(b) becomes almost constant over a broad spectral region in comparison to that for the straight waveguides [see Fig. 1(b)]. The Taylor expansion of the effective coupling coefficient is 

\[ c_0^{\text{eff}} = 9.96 \text{ mm}^{-1}, \ c_1^{\text{eff}} = -0.0076 \text{ fs } \mu \text{m}^{-1}, \ c_2^{\text{eff}} = -14.2 \text{ fs}^2 \mu \text{m}^{-1} \]

Although the
quadratic coupling dispersion is slightly increased in comparison to the straight waveguide array, the linear coupling dispersion, which is the main temporal reshaping driver for 100 fs long pulses in such structures, is suppressed by two orders of magnitude compared to the straight waveguides. In Fig. 3(c) we plot the supermode propagation constants for the curved waveguide arrays with three coupled nanowires calculated with the use of the effective coupling coefficient. The propagation constants for the three supermodes now have similar slopes, which suggests that short-pulse break-up due to coupling would be suppressed.

We now calculate the intensity evolution of a 100 fs transform-limited pulse coupled to the left nanowire of the periodically curved waveguide array using the Eqs. (2)-(4). We see in Figs. 4(a-c) that as a result of vanishing coupling dispersion the temporal pulse break-up is suppressed, and a pulse can now be switched as a whole between the waveguides. Thus the temporal and the spatial dispersion in nanowire waveguide arrays can be controlled independently via single waveguide dispersion engineering and periodic waveguide bending.

These results demonstrate that spatio-temporal dispersion engineering in high-index-contrast nanowire waveguide arrays can be efficiently realized through the introduction of periodic waveguide bending, which can enable flexible spatio-temporal manipulation of femtosecond pulses. We anticipate that these results will open novel approaches to on-chip all-optical light control. This approach can also be useful for enhanced parametric frequency conversion [2] and broadband photon-pair generation and quantum walks [10].
