Abstract

During running at a constant speed, the optimal stride frequency (SF) can be derived from the u-shaped relationship between SF and heart rate (HR). Changing SF towards the optimum of this relationship is beneficial for energy expenditure and may positively change biomechanics of running. In the current study, the effects of speed on the optimal SF and the nature of the u-shaped relation were empirically tested using Generalized Estimating Equations. To this end, HR was recorded from twelve healthy (4 males, 8 females) inexperienced runners, who completed runs at three speeds. The three speeds were 90%, 100% and 110% of self-selected speed. A self-selected SF (SFself) was determined for each of the speeds prior to the speed series. The speed series started with a free-chosen SF condition, followed by five imposed SF conditions (SFself, 70, 80, 90, 100 strides min⁻¹) assigned in random order. The conditions lasted 3 minutes with 2.5 minutes of walking in between. SFself increased significantly (p < 0.05) with speed with averages of 77, 79, 80 strides min⁻¹ at 2.4, 2.6, 2.9 m s⁻¹, respectively). As expected, the relation between SF and HR could be described by a parabolic curve for all speeds. Speed did not significantly affect the curvature, nor did it affect optimal SF. We conclude that over the speed range tested, inexperienced runners may not need to adapt their SF to running speed. However, since SFself were lower than the SFopt of 83 strides min⁻¹, the runners could reduce HR by increasing their SFself.

Introduction

Running speed is the product of stride frequency (SF) and stride length (SL), and both are shown to increase when runners increase their speed. SF, expressed in strides per minute (strides·min⁻¹), describes the duration of a complete stride cycle (left and right step). SF consequently relates to many biomechanical aspects of running [1–15]. Hence, SF has received considerable attention from both scientific and practical perspective. Although many sports-watches provide instantaneous SFs, they do not yet provide feedback about the SF at which energy cost for the individual runner is minimized: SFopt, the optimal SF at a given speed. In practice, as a rule of thumb and independent of running speed, runners are often advised to run at 90 strides·min⁻¹ [16]. This recommendation is based on the observation that, for all
running distances, elite runners seem to use a SF of at least 90 strides-min⁻¹. However, it is
doubtful that this SF is optimal for every runner at every speed, as 90 strides-min⁻¹ is sub-
stantially higher than most self-selected stride frequencies (SFₜₐₗ) and even higher than SFₜₐₗ,opt reported in literature [4,17]. Cavanagh et al [18] suggested that only (individual) physiological
evidence of a discrepancy between preferred and SFₜₐₗ,opt should be used to advise changes
in SF.

To calculate SFₜₐₗ,opt, previous studies typically imposed SF or SL and recorded oxygen
consumption while participants ran at a constant submaximal speed [4,19–23]. The relation
between SF and oxygen consumption was fitted per individual using a second order
polynomial, resulting in a u-shaped relation, where the SF with minimal oxygen consump-
tion was considered to be optimal [1,19,21–23]. These studies showed that experienced
runners tend to run with SFs close to their SFₜₐₗ,opt [19,23,24], while inexperienced runners
appear to run with SFs below their SFₜₐₗ,opt [19]. As an alternative to measuring oxygen con-
sumption, De Ruiter et al [19] showed that heart rate (HR) can also be used to determine
the SFₜₐₗ,opt.

Several biomechanical mechanisms may explain the reduction of energy cost that
occurred when individual runners slightly increased their SFs. For example, higher SFs are
associated with reduced vertical oscillations [1–3], shorter ground contact [1,2], increased leg
stiffness [1] and reduced horizontal braking forces [4–6], which are all factors suggested to be
important for economical running [5,8]. In addition, increasing SF changes the kinetics in
the gait cycle change in ways that have been suggested to reduce injury risk [6,13–15]. For
example, higher SFs reduce anterior foot placement [3,4], impact forces [9], vertical acceler-
ations [4,7,11] [10], knee extension moments at initial contact [12] and negative energy at the
hip and knee [3,7]. Among runners injury incidence rates as high as 79.3% have been
reported [25] and changing running technique may be effective to reduce the injury risk.
Inexperienced runners may be particularly susceptible to injuries because of their lower toler-
ance to impact forces [26,27].

HR, speed and SF are measured by many commercially available sports devices, which
would in principle allow runners to determine their own SFₜₐₗ,opt. Reviewing results from previ-
ous studies revealed that both SFₜₐₗ and SL increase when individual runners increase their
speed [1,4,9,14,19,21,22,28–33]. Therefore, it can be expected that SFₜₐₗ also increases with
speed (Fig 1c and 1d). To attain higher speeds, energy cost per unit of time will increase. HR
consequently approaches its physiological maximum and the parabolic relation between SF
and HR may flatten (Fig 1a and 1b). A relatively steep parabola with a profound optimum may
then be apparent at low speeds. At higher speeds, the curve is expected to flatten, which would
make the estimation of SFₜₐₗ,opt less robust. However, we hypothesize that for normal training
intensities this flattening is of no significance, since for healthy individuals, heart rate increases
linearly with exercise load and only plateaus just before maximal oxygen consumption is
reached [34]. The effect of speed on SFₜₐₗ may seem obvious. However, to our knowledge, the
effect of speed on the calculation of SFₜₐₗ has never been tested systematically. Understanding
the effect of speed on the SF-HR relation is required to develop a method to provide runners
with feedback on their SFₜₐₗ during training.

The aim of this study is to understand the practical consequence of changing speed on the
relation between SF and HR in running. To this end, we use a group-based analysis. We
hypothesize that within a speed range that is representative and attainable for inexperi-
enced runners: 1) a speed-specific parabolic relation exists between SF and HR; 2) SFₜₐₗ,opt increases
with speed; 3) the parabolic SF-HR relation does not flatten at higher speeds; 4) inexperienced
runners select SFs below the determined optimum.
Methods

Four models were tested to evaluate the effect of speed on the calculation of SF$_{\text{opt}}$ (see Fig 1). SF$_{\text{opt}}$ was defined as the SF where HR (response variable) was minimal according to the model. The models are described with the following equations:

\[
\text{HR} = b_0 + b_1 \cdot \text{SF} + b_2 \cdot \text{SF}^2 + b_3 \cdot V \quad \text{(Model 1)}
\]

\[
\text{HR} = b_0 + b_1 \cdot \text{SF} + b_2 \cdot \text{SF}^2 + b_3 \cdot V + b_4 \cdot \text{SF} \cdot V \quad \text{(Model 2)}
\]

\[
\text{HR} = b_0 + b_1 \cdot \text{SF} + b_2 \cdot \text{SF}^2 + b_3 \cdot V + b_5 \cdot \text{SF}^2 \cdot V \quad \text{(Model 3)}
\]

\[
\text{HR} = b_0 + b_1 \cdot \text{SF} + b_2 \cdot \text{SF}^2 + b_3 \cdot V + b_4 \cdot \text{SF} \cdot V + b_5 \cdot \text{SF}^2 \cdot V \quad \text{(Model 4)}
\]

Model 1 assumes a parabolic relationship ($b_1$, $b_2$) with a speed-dependent offset ($b_3$). Model 2 assumes that SF and consequently SF$_{\text{opt}}$ increases linearly with speed ($b_4$). Model 3 assumes that speed changes the parabolic relation between SF and HR ($b_5$). More specifically, it reflects a flattening of the curve at higher speeds. Model 4 assumes both a linear speed dependency of SF as described by Model 2 ($b_4$) and a flattening of the curve as described by Model 3 ($b_5$). The model regression coefficients were tested for significance in order to establish their contribution to the fit. Models with significance on all predictors are potentially valid.

Participants

Twelve healthy (4 males, 8 females) inexperienced runners participated (23.3 ± 3.4yrs, 175 ± 1.1cm, 69.6 ± 13.0kg) in the present study, after given written informed consent approved by the Institutional Review Board at the Vrije Universiteit Amsterdam. The study was approved by the local ethics committee (in Dutch: Ethische Commissie
Bewegingswetenschappen) in accordance with the guidelines set out in the Helsinki Declaration regarding human research.

Participants ran no more than once a week and participated at least once a week in sports activities that did not involve running (4.8 ± 2.6 training hours per week). Inexperienced runners were chosen for this study since they were expected to benefit most from altering their SF.

[19]

Instrumentation

Participants ran on a treadmill (N-Mill, ForceLink, Culemborg, Nederland). Strides were detected using a custom written Matlab program analysing the tri-axial acceleration data from sensors (MPU-9150, +/- 16.0g, 500Hz, 35 x 25 x 11 mm, Invensense, San Jose, USA) placed on the heels of the participants. HR was measured using a HR monitor (Suunto t6d, Vantaa, Finland). To synchronize the SF-data with the HR-data, participants jumped causing a peak in the acceleration signal, while simultaneously starting the HR-monitor.

Protocol

All measurements took place on the same day. Prior to testing, self-selected running speed ($V_{100\%}$) was determined as follows. The participants ran for 5 minutes at a speed of 2.22 m·s$^{-1}$ (8 km·h$^{-1}$). Subsequently, every 20 s speed was increased by 0.14 m·s$^{-1}$ (0.5 km·h$^{-1}$). Participants were asked to indicate when they reached a speed that they felt able to sustain for 10 minutes with moderate to strong effort ratings on the RPE-scale. The protocol consisted of three separate speed series in fixed order: (i) Starting with the self-selected speed ($V_{100\%}$), followed by (ii) 90% of self-selected speed ($V_{90\%}$) and finally, (iii) 110% of self-selected speed ($V_{110\%}$). This was done to minimize the risk of participants not being able to complete the protocol due to the expected fatigue expected at $V_{110\%}$.

Within each speed series, the participants ran first for 3 minutes without instructions to get familiarized with running on the treadmill and to determine the $SF_{self}$. Where $SF_{self}$ was calculated as the mean SF over the last minute of familiarization trial. After the 3 minutes familiarization, participants had 5 minutes of rest followed by six blocks of 3 minutes. The first block was intended as warming-up without an imposed SF. The consecutive blocks were conditions with imposed SFs (i.e. 70, 80, 90, 100 strides·min$^{-1}$ and $SF_{self}$) administered in randomised order (without replacement) for each participant. Thus, the order of SF conditions differed among participants, but the SF condition order at each of the three speeds was kept consistent for each participant.

Each block was followed by 2.5 minutes of walking at 1.11 m·s$^{-1}$ (4 km·h$^{-1}$). Participants rested for 15 minutes after each of the speed series. SF was imposed by lines projected on the treadmill perpendicular to the running direction (visually similar to a zebra crossing) using a projector. The lines were projected across the full width of the treadmill and from 2 m in front of the participants to 1 m behind the centre of the treadmill and approached the runner with the speed of the treadmill. Participants could choose to either step on or step between the projected lines as long as they were consistent.

Data analysis

Data were synchronized and pre-processed using Matlab 2015. For every 3-minute block, the median SF and median HR were calculated over the last minute. Generalized Estimating Equation (GEE) modelling was used to evaluate the four models. The dependency of the variables speed, SF, and HR is expected to differ between individuals [23]. By choosing an exchangeable correlation structure, GEE offers the possibility to assume that all observations within the
same individual are equally correlated. GEE is a group-based approach that can take the
dependency of observations within individuals over conditions into account. The GEE does
not assume normally distributed data. The GEE was performed using SPSS 22.0. In order to
measure how well the participants were able to run at the imposed stride frequencies, a per-
centage error (SF\textsubscript{error}) was calculated from the imposed versus the observed SF (Eq 1).

\[
SF_{\text{error}} = \frac{(SF_{\text{observed}} - SF_{\text{imposed}})}{SF_{\text{imposed}}}
\]

Differences in SF\textsubscript{self} between speeds were tested using a Friedmans's test with a significance
level of 0.05. Post hoc analysis was done using Wilcoxon signed ranks test. The protocol was
designed to reduce exercise load while simultaneously minimize the variation in HR between
blocks when the SF-conditions were not present. Nevertheless, exercise load was relatively
high and body temperature was expected to increase. Consequently, we did not expect that HR
would completely level off during the last minutes of the exercise steps. To indicate the level of
steady-state, the slope of HR during the last minutes of the exercise steps was calculated using
a bi-square linear fit.

**Results**

Only in **Model 1** were all parameters found to be significant (Table 1) and thus the relation
was best described by **Model 1.** **Model 1** indicated that the relation between SF and HR can be
described by separate parabolic relations at all speeds. **Model 2** predicted that SF\textsubscript{opt} would
increase with speed, but the predictor did not appear to be significant (**Model 2, b\textsubscript{4}: p = 0.090**).
**Model 3** predicted a flattening of the curve at higher speeds, but also the quadric SF-term did
not significantly interact with speed (**Model 3, b\textsubscript{5}: p = 0.080**). Finally, **Model 4**, predicted both
an increase of the optimum and a flattening of the curve with increasing speed, but also this
model did not significantly improve the fit (**Model 4, b\textsubscript{3}: p = 0.077, b\textsubscript{4}: p = 0.056, b\textsubscript{5}: p = 0.053**).

Based on **Model 1**, the heart rate at SF\textsubscript{opt} can be expressed as: \(HR = 370.59 + -6.223 \cdot SF + 0.0375 \cdot SF^2 + 22.016 \cdot V\). The SF\textsubscript{opt} is obtained as the minimum in the HR-SF relationship, calculated as the SF derivative of HR. Therefore, SF\textsubscript{opt} = 6.223 / (2 * 0.0375), which yields SF\textsubscript{opt} = 83 strides min\textsuperscript{-1} for all speeds used in this study. Due to technical problems, data of one partici-
pant were missing at V\textsubscript{100%} and V\textsubscript{110%}, while for another participant the data at V\textsubscript{90%} were
missing, resulting in eleven subjects per speed condition and 69, 64, and 61 observations,
respectively.

**Table 1. Significance of the model parameters.**

| Model 1 | | | Model 2 | | | Model 3 | | | Model 4 | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | B | Std.Error | P-value | B | Std.Error | P-value | B | Std.Error | P-value | B | Std.Error | P-value |

| b\textsubscript{3} (V) | 22.016 | 3.833 | p<0.01 | 63.669 | 2.144 | p<0.01 | 44.022 | 10.413 | p<0.01 | -379.983 | 214.795 | 0.077 |
| b\textsubscript{4} (SF * V) | - | - | - | - | - | - | - | - | - | - | - |
| b\textsubscript{5} (SF\textsuperscript{2} * V) | - | - | - | - | - | - | - | - | - | - | - |

The parameter terms \(b_{0-5}\) are based on the following equation:

\[
HR = b_0 + b_1 \cdot SF + b_2 \cdot SF^2 + b_3 \cdot V + b_4 \cdot SF \cdot V + b_5 \cdot SF^2 \cdot V
\]

https://doi.org/10.1371/journal.pone.0184273.t001
Median speed values (25 and 75 percentiles) for the three speed categories respectively were: 2.38 (2.38–2.56), 2.6 (2.5–2.9), and 2.9 (2.8–3.1) m\(\text{s}^{-1}\), with SF\(_{\text{self}}\): 77 (75.5–78.5); 79 (76.5–81.0); 80 (77.5–81.0) strides\(\cdot\)min\(^{-1}\) and HR: 166 (155–178); 172 (165–176.); 177 (167–180) beats\(\cdot\)min\(^{-1}\). SF\(_{\text{self}}\) differed significantly between speed conditions (\(X^2(2) = 6.686, p = 0.035\)) and post-hoc analysis showed a significant difference only between V\(_{90}\%\) and V\(_{100}\%\) (Z = -2.354, p = 0.019). Note that at each speed, SF\(_{\text{self}}\) was below the optimum of 83 strides\(\cdot\)min\(^{-1}\) predicted by Model 1 (Fig 2) by 6%, 5%, 2% for V\(_{90}\%), V_{100}\%, and V_{110}\%\), respectively. Only one participant ran at about 90 strides\(\cdot\)min\(^{-1}\) at all speeds, which clearly was above the calculated optimum of 83 strides\(\cdot\)min\(^{-1}\).

Participants did not always succeed in running at the imposed SFs (Fig 3). Deviations between the calculated SF and the imposed SF were similar between conditions 2.5\(\pm\)4\% (mean\(\pm\)sd), with a tendency towards higher errors in the V\(_{90}\%) and V\(_{100}\%) conditions compared to the V\(_{100}\%\)-condition. Moreover, errors increased for more extreme SF-conditions (e.g., 70 and 100 strides\(\cdot\)min\(^{-1}\)).

**Discussion**

The aim of this study was to examine the effect of speed on the relationship between SF and HR within an ecologically valid speed range for inexperienced runners. For all speeds, the SF-HR relation could be described by a parabolic curve; these curves shared an SF\(_{\text{opt}}\) at 83 strides\(\cdot\)min\(^{-1}\). The curve did not flatten as expected and SF\(_{\text{opt}}\) did not significantly increase with speed. Therefore, it was not needed to extend Model 1 with additional parameters as in Models 2–4. To our knowledge, the effect of speed on the calculation of SF\(_{\text{opt}}\) has not been studied before. Previous studies have used direct curve-fitting procedures on individual observations.
Instead, in this study we used a group-based analysis (GEE) as a more robust alternative.

The optimum of 83 strides min⁻¹ determined here, does not differ much from previously calculated SF_{opt}. In a group of inexperienced runners, De Ruiter et al [19] found an optimum of 84.9 strides min⁻¹ at an average speed (2.67 m s⁻¹) comparable to the average self-selected speed in the present study. The difference of 1.9 strides min⁻¹ is relatively small and can be attributed to differences in the analytical approach, methodology, and variance between subjects [19, 23]. Note that in both studies, SF_{opt} was considerably lower than the 90 strides min⁻¹ proposed by Daniels [16], which is currently often used as a reference in practice. As a rule of thumb, it seems more appropriate to advise inexperienced runners with speeds between 2.4 to 2.9 m s⁻¹ to run at SF near 83 strides min⁻¹.

The speed range used in this study was intended to reflect common exercise intensities and based on a self-rated intensity score during a pre-test. HR was used as an estimate for intensity and energy cost. HR ranged on average between 166 and 176 beats min⁻¹ over the speeds, which seems an appropriate reflection of regular endurance training intensities. HR did not completely level off during the SF-conditions. However, the calculated HR slope over the last minute was small (1.4 beats min⁻¹). Besides, even during truly steady state conditions, thus while running below lactate threshold and with longer (5 min) exercise blocks, HR does not completely level off [36]. Therefore, we believe that HR values and thus the speed range used in this study sufficiently reflect training intensities of this group of runners.

Still, the speed range tested was relatively small (2.4 to 2.9 m s⁻¹, i.e. 8.6 to 10.4 km h⁻¹). Measured SF_{self} changed significantly with speed, but only between the first two speeds (V_{90%} and V_{100%}). The calculated SF_{opt} did not change with speed, but the interaction effect of speed and SF was close to significance (p = 0.09). In accordance with the non-significant interaction between SF and speed in the present study, Weyand et al [33] also did not observe significant changes in SF_{self} within a speed range of 2 to 4 m s⁻¹. Only for larger speed ranges did SF_{self} change.
increase significantly [33]. Mercer et al [22] also did not find a significant effect of speeds from 3.13, 3.58, 4.02 m·s⁻¹ on the relation between SF and oxygen consumption. Note that their goal was not to determine an SF_{opt}, but still they used three (non-randomized SF) conditions. In the present study, the median values of SF_{self} at the different speeds revealed a trend and the p-values for the interaction terms of speed on SF in Models 2 and 4 were small. Post-hoc analysis revealed that the study was slightly underpowered and hence a type II error cannot be excluded. Therefore, Model 1 may not hold when tested over a larger speed range or with a larger group of participants. Especially, for more experienced runners the speed range will likely be larger and it is not unlikely that speed will affect their SF_{opt}.

Similarly, although we did not find flattening of the SF-HR relation at higher speeds in the present study, a flattening may occur in more experienced runners who are able to run at higher percentages of maximal HR for longer durations.

Interestingly, our results suggest that the participants could immediately reduce their heart rates when they would be running at higher SFs, closer to 83 strides·min⁻¹. Similarly, in previous studies [4,19–21], runners would reduce oxygen cost immediately by increasing their SF. It remains to be investigated whether the energy sparing effect will increase even more after a period of habituation and/or training at higher SFs. As far as we know, for endurance intensities, there are no studies suggesting that runners should run at SFs other than determined by the energetic optimum. Since, it is currently unknown what the reason is for inexperienced runners to run at SFs below the energetic optimum, understanding of what limits adaptation of SF towards the optimum may help to improve learning strategies. It might be argued that coordination may limit the attainable SF, as higher SFs require faster muscle recruitment and derecruitment. From this study and also from the pilot experiments (where a metronome was used) it became clear that some runners did find it very hard to stabilize newly imposed SFs. Participants also made more errors at the extreme imposed SFs. Similar errors were found in a previous study in which SF was imposed by the use of a metronome [18]. However, the low number of errors in the 80 strides·min⁻¹ condition suggests that running at SFs of 83 strides·min⁻¹ is unlikely to be hampered by limitations in coordination.

There are many individual factors that could explain the large inter-individual differences in SF_{self}. For example, SF at a given speed has been found to decrease with fatigue [37] and in a subject-specific manner [20]. In addition, damping properties of footwear [1,38–40] and slope [31,41] could affect SF. Effects of anthropometric factors such as body composition or leg length are small in comparison with other factors [28]. In line with this, it was recently shown that a change in SF_{opt} resulted only after adding as much as 1 kg mass to each ankles [42]. The different factors can be categorized in individual characteristics (e.g., neuromuscular control, fibre type, body weight or mass), time-varying variables (e.g., speed, fatigue), and environmental circumstances (e.g., (shoe) damping, surface, slope, hypoxia, heat [43]). Note that most of these factors will be reflected in individual energy cost and that only some of them will vary sufficiently within a training to take into account when providing feedback. Nevertheless, it may be worthwhile to investigate their effects on the SF-HR relation while taking speed into consideration to understand differences between groups. Given the high inter-individual differences in SF_{self}, the many possible factors influencing SF, not to mention the importance of variability [44], the advice to run at 83 strides·min⁻¹ should not be generalized to all individuals or to all running conditions.

In the current study, we used a group-based approach in order to get a robust fit. Future studies could apply the proposed models to a larger population, which would allow for better generalization, or study the effects speed over a larger speed range to understand the differences in running experience. In addition, it is worthwhile to study the reason for inexperienced runners to select SFs below the energetic optimum, to what extent, and how quickly
these runners adapt SF_{self} towards the energetic optimum with specific training. Nevertheless, since commercially available running equipment can already measure speed (by GPS), HR, and SF, it may already be possible to use the logged data from such equipment to determine SF_{opt}.

**Conclusion**

We conclude that SF_{opt} is relatively stable at the speeds used by inexperienced runners. The speed range in this study was determined individually and was intended to reflect the habitual endurance running intensities of inexperienced runners. For almost all the participants, the SF_{self} was substantially lower than the optimum of 83 strides-min^{-1}. Therefore, the results suggest that inexperienced runners can obtain direct energetic benefit from increasing their SFs. It seems of lesser importance that runners adapt their SF instantaneously to specific speeds, since the commonly used speed range of inexperienced runners will be rather limited. Intra-individual differences are high and contextual differences may constrain SF_{opt}; therefore, the generalized advice to run at 83 strides-min^{-1} should be avoided and feedback on SF should be determined individually. In addition, the current study does not rule out the possibility that SF_{opt} may increase with speed over larger speed ranges. Future studies could extend this work by applying the models on data logged by commercial devices to provide runners with individualized feedback on their SF_{opt}.
