**Abstract.** Chemoattractants differ in their capacity to stimulate neutrophils to adhere to and to migrate through matrices containing fibrin. Formyl methionyl leucyl phenylalanine (fMLP) stimulates neutrophils to adhere closely to, but not to migrate into, fibrin gels. Leukotriene B4 (LTB4) stimulates neutrophils to adhere loosely to and to migrate through fibrin gels. We report that α5β1 integrins regulate the different migratory behaviors on fibrin gels of neutrophils in response to chemoattractants. fMLP, but not LTB4, activated neutrophil β1 integrins, as measured by binding of mAb 15/7 to an activation epitope on the activated neutrophil.

**Key words:** chemotaxis • neutrophils • integrins • fibrin • chemoattractants

**Leukocyte** chemotaxis is regulated by the interactions of soluble or surface-bound chemoattractants/chemokines with cognate receptors on the leukocytes. These interactions generate intracellular signals that activate one or more of the leukocyte’s adhesion-promoting receptors, thereby enabling these cells to adhere to or migrate through endothelia, epithelia, and extracellular matrices.

Neutrophils (polymorphonuclear leukocytes, PMN) express a number of different adhesion-promoting surface receptors, including β1 and β2 integrins. β2 integrins assume an “activated” conformation when chemoattractants, chemokines, cytokines, or growth factors bind to specific receptors for these substances on PMN (Diamond and Springer, 1994; Premack and Schall, 1996). Activation increases the capacity of β2 integrins to bind cognate ligands on cells or matrix proteins, thereby regulating PMN adhesion to and migration through endothelia (Smith, 1993; Springer, 1995), epithelia (McCormick et al., 1995), layers of synovial fibroblasts (Gao et al., 1995; Gao and Issekutz, 1996), and extracellular matrices (Wright et al., 1988; Loike et al., 1991, 1992, 1995). The central roles played by β2 integrins in PMN adhesion and chemotaxis in vivo are illustrated by the multiple derangements of PMN function in humans with the inherited disorder leukocyte adhesion deficiency type 1, in which there is partial to complete absence of β2 chains (Anderson and Springer, 1987), and in mice rendered functionally or genetically deficient in α5β2 (CD11b/CD18) integrin (Tang et al., 1997).

PMN also express β1 integrins, primarily α3β1, α6β1, and α8β1, but also very low levels of α5β1 (Gao et al., 1995; Gresham et al., 1996) that participate in PMN adhesion, migration, and phagocytosis. For example, C5a, a cleavage product of the fifth component of complement, and PMA stimulate α5β1-dependent PMN adherence to fibrinectin.
Chemoattractant-activated β1 integrins work in concert with αmβ2 (CD11b/CD18) integrins to mediate phagocytosis of particles coated with C3bi by PMN (Pommier et al., 1983; Wright et al., 1984; Brown, 1992). β1 integrins also mediate chemotaxis of platelet activating factor-stimulated rat PMN (Weir et al., 1998).

We reported previously (Loike et al., 1995) that different chemoattractants specify qualitatively distinct PMN responses when PMN contact specific matrix proteins. For example, PMN stimulated with formyl methionyl leucyl phenylalanine (fMLP) or tumor necrosis factor-α form zones of close apposition on fibrin and do not migrate through fibrin gels, whereas PMN stimulated with leukotriene B4 (LTB4) or interleukin 8 (IL-8) form zones of loose apposition on fibrin and migrate efficiently into and through fibrin gels (Loike et al., 1995). All of these chemoattractants activate PMN β2 integrins (Diamond and Springer, 1994; Premack and Schall, 1996) and induce integrin–ligand interactions with ligands on fibrin. Therefore, it seemed unlikely that the different effects of fMLP and LTB4 on chemotaxis are mediated by integrins.

Materials and Methods

Reagents

Rhodamine-conjugated polyethylene glycol of 3.5 kD (R-h-PEG 3.5 kD) and 10 kD (R-h-PEG 10 kD) were prepared as described (Loike et al., 1993, 1995). Sources of antibodies and peptides were as follows: mouse anti-β1 (PAC10) and the peptides GRGDSP and GRGESP were from Gibco BRL. Mouse anti-human α4 (LeuM5) was from Ortho-Teknika Inc. Mouse anti-human αMβ2 (MAC-1) was from Uplatec Biotechnology Co. Mouse anti-human α5 (SA 1 M), rat anti-human α3 (G0H 3), mouse anti-human α3 (H-P2/1), and mouse anti-human β3 integrin (S2Z1) were from Immunotech. Phycocerythrin-conjugated F(ab)2 anti-mouse IgG was from Jackson Immunoresearch. Mouse anti-β3 (PDM13) was from Biosource International. Mouse anti-β2 (M A 1) was from Chemicon International. Alexa 488-conjugated F(ab)2 anti-mouse IgG was from Molecular Probes. LTB4, fMLP, PMA, thrombin, and Ficol-Hypaque were from Sigma Chemical Co. Mouse anti-chicken β1 integrin (CSAT) and mouse monoclonal anti-human β3 integrin (A1B2) were generous gifts from Dr. Clayton Buck (University of California, San Francisco, CA). Mouse mAb 15/7, which recognizes an activation epitope on human β3 integrins (Bohnsack et al., 1995), was from A thena Neurosciences. Mouse mAb 1B4, which blocks the ligand-binding domains of human β3 integrins (Wright et al., 1983), was a generous gift from Dr. Samuel D. Wright (Merck, Rahway, NJ). PPA CK was from Calbiochem-Novabiochem.

Preparation of Boyden-type Chemotaxis Chambers

Gels, ~1 mm thick, composed of fibrin, Matrigel, or collagen type IV, were formed in cell culture inserts (pore sizes 3 or 8 μm) from Becton Dickinson as described (Loike et al., 1995). Fibrin gels were gently washed with PBS to remove any residual PPA CK.

PMN Adhesion and Closeness of Apposition to Fibrin-coated Surfaces

Fibrin/fibrinogen-coated surfaces were prepared as described (Wright et al., 1988; Loike et al., 1992, 1993, 1995) and PMN adhesion was measured by phase-contrast microscopy. Close apposition of PMN to fibrin/fibrinogen-coated surfaces was defined as exclusion of Rh-PEG 10 kD from zones of contact between PMN and fibrin/fibrinogen measured by fluorescence microscopy as described (Loike et al., 1993).

PMN Migration

PMN were prepared as described (Wright et al., 1988) from fresh heparinized blood from healthy adult donors after informed consent. PMN used in these experiments were >95% pure as determined by Wright-Giemsa staining (Wright et al., 1988). 10⁶ PMN in 100 μl of PBS supplemented with 5.5 mM glucose and 0.1% human serum albumin (PBSG-HSA) were placed in the upper compartment of each insert and incubated for 0–6 h at 37°C in a humidified atmosphere containing 95% air/5% CO₂. At the times and concentrations specified, chemoattractants, antibodies, and/or peptides were added to the top and/or bottom compartments in 500 μl of PBSG-HSA. At the end of incubations, chambers were shaken to dislodge PMN from the lower surface of the inserts. The medium in each lower compartment was collected and its content of PMN was determined using a Coulter counter (Loike et al., 1995). Unless otherwise indicated, all values reported are the average of six different samples from at least three independent experiments.

Flow Cytometric Analysis

PMN (10⁵ cells/200 μl of PBSG-HSA) were incubated in suspension at 37°C for 30 min in the presence or absence of fMLP (10⁻⁷ M) or LTB4 (10⁻⁷ M), transferred to 96-well polystyrene tissue culture microtiter plates (Corning), incubated for 30 min at 4°C in 200 μl PBSG-HSA containing the indicated primary antibody (2 μg/ml), washed three times with PBSG-HSA at 4°C, further incubated for 30 min at 4°C with either Alexa 488-conjugated or phycocerythrin-conjugated rabbit anti-mouse F(ab)2 in 200 μl PBSG-HSA, washed three times again with PBSG-HSA at 4°C, and resuspended at 4°C in 300 μl PBS containing 2% BSA and 0.3 mg/ml propidium iodide to determine cell viability. The contribution of dead cells (usually <2%) was removed from the final data analysis. The mean fluorescence intensity of 3–5 × 10⁴ cells was determined using a Becton Dickinson FACSCalibur®.

Results

PMN Chemotaxis through Matrigel and Fibrin Gels

PMN chemotaxis through three-dimensional gels composed...
of reconstituted basement membrane proteins containing collagen IV, laminin, and fibronectin (Matrigel; Fig. 1), or collagen I (Loike et al., 1995) in response to a gradient of fMLP or LTB4. In contrast, PMN chemotaxis through fibrin gels or plasma clots is dependent upon the specific chemoattractant used. fMLP-stimulated PMN do not migrate through fibrin gels or plasma clots, whereas LTB4-stimulated PMN do (Fig. 2A; Loike et al., 1995). Checkboard analyses confirmed that PMN migrate through these gels in response to a chemoattractant gradient (Loike et al., 1995). Placement of equimolar concentrations of both fMLP and LTB4 into the bottom chambers inhibited PMN from migrating through fibrin gels (Fig. 2A; Loike et al., 1995), confirming that fMLP’s effect is dominant over LTB4’s effect.

Commercial fibrinogen contains small amounts of fibronectin and vitronectin. To test whether matrix components other than fibrin are responsible for inhibiting migration of fMLP-stimulated PMN through fibrin gels and plasma clots, we performed additional experiments using fibrin gels formed from purified fibrinogen that contained no detectable fibronectin, plasminogen, Factor XIII, or vitronectin. PMN stimulated with LTB4, but not with fMLP, migrated through gels formed from purified fibrinogen (Fig. 2B). Moreover, collagen I gels (60 µg/ml) each containing 10 µg of purified fibronectin did not affect the migration of either fMLP- or LTB4-stimulated PMN, whereas the addition of fibronectin to such gels blocked migration of fMLP-stimulated PMN (data not shown). These results are consistent with reports (Asakura et al., 1997; Farrell and al-Mondhiry, 1997; Suehiro et al., 1997; Miettinen et al., 1998) that fibrin(ogen) contains sequences that are ligands for β1 integrins, and confirm that fibrin is the matrix component that inhibits migration of fMLP-stimulated PMN.

**Effects of Antibodies against β1 and β2 Integrins on PMN Chemotaxis through Fibrin Gels and Matrigel**

To examine the roles of β1 and β2 integrins in PMN migration through Matrigel (Fig. 1), or fibrin (Figs. 2A and 3), we added antibodies that block β1 or β2 integrins to the upper compartment of Matrigel or fibrin-coated inserts together with PMN and measured the number of PMN that migrated into the lower compartment in response to fMLP or LTB4. As expected, mAb IB4, directed against β1 integrins (Wright et al., 1983), blocked PMN migration through Matrigel (Fig. 1) or fibrin gels (Fig. 2A) in response to LTB4. A nitbody IB4 also blocked fMLP-stimulated PMN migration through Matrigel (Fig. 1), and did not alter fMLP’s inhibitory effect on PMN chemotaxis through fibrin gels (data not shown). These results are consistent with previous reports (Diamond and Springer, 1994; Springer, 1995; Premack and Schall, 1996) that anti-β1 integrin antibodies block PMN migration through endothelia and through gels formed by a variety of extracellular matrix proteins.

In contrast, mAbs AIIb2 (Bohsack et al., 1990) and P4C10 (Carter et al., 1990), which block the common β chain of β1 integrins (CD29), had no effect on fMLP- or LTB4-stimulated chemotaxis through Matrigel (Fig. 1), or on LTB4-stimulated PMN migration through fibrin gels.
not human reversed fMLP’s inhibitory effect on PMN chemotaxis as described in Fig. 1.

The Journal of Cell Biology, Volume 144, 1999 1050

Table I. Effect of RGD-containing Peptides on fMLP- and LTB4-stimulated PMN Chemotaxis through Fibrin Gels

| Additions Chemoattractant | PMN in lower compartment (× 10⁻²) |
|--------------------------|----------------------------------|
| None                     | fMLP 3 ± 1                       |
| GRGDSP                   | fMLP 50 ± 5                      |
| GRGESP                   | fMLP 2 ± 1                       |
| None                     | LTB4 135 ± 30                    |
| GRGDSP                   | LTB4 170 ± 50                    |
| GRGESP                   | LTB4 110 ± 40                    |

PMN were preincubated for 30 min at 4°C with PBSG-HSA alone or containing 1 mg/ml GRGDSP or GRGESP before adding the mixture to the upper compartment of chemotaxis chambers. LTB4 (10⁻² M) or fMLP (10⁻² M) was added to the lower compartment, the chambers were incubated at 37°C for 6 h, and the number of PMN that migrated into the lower compartment was determined, all as described in Fig. 1. Values represent the average ± SEM of triplicate samples from three experiments.

The peptide GRGDSP blocks the interaction of β₁ integrins with RGD ligands on matrix proteins (Pierschbacher and Ruoslahti, 1987). Like antibodies against β₁ integrins, addition of GRGDSP peptide to the medium allowed fMLP-stimulated PMN to migrate through fibrin gels (Table I). Control experiments showed that GRGESP peptide, which does not block binding of β₁ integrins to fibronectin or other RGD-containing matrix proteins (Pierschbacher and Ruoslahti, 1987), did not reverse the inhibitory effect of fMLP on PMN migration through fibrin gels (Table I). Neither peptide affected the number of PMN that migrated through fibrin in response to LTB4 (Table I) or through Matrigel in response to fMLP (Fig. 3 B).

Effects of Antibodies against β₁ and β₂ Integrins on Adhesion of Chemoattractant-stimulated PMN to Fibrin

PMN were incubated in control medium or in medium containing fMLP or LTB4 and allowed to adhere to fibrin-coated 96-well plates. In the absence of chemoattractant <1% PMN adhered to fibrin (data not shown). Over 40% of fMLP-stimulated PMN and ~50% of LTB4-stimulated PMN adhered to fibrin. mAb 15/7, which blocks the ligand-binding sites of three different β₂ integrins (α₅β₂, α₅β₁2, and α₅β₂), Wright et al., 1983; Loike et al., 1991), inhibited adhesion of fMLP- or LTB4-stimulated PMN to fibrin by 75–80% (Fig. 4). In contrast, mAb 15/7, which blocks the ligand-binding sites of β₁ integrins (Bohsack et al., 1990), had no significant effect on the number of fMLP-stimulated PMN that adhered to fibrin, and enhanced by ~25% adhesion of LTB4-stimulated PMN to fibrin (Fig. 4). These experiments show that β₁ integrins are the primary PMN surface receptors that mediate adhesion of chemoattractant-stimulated PMN to fibrin.

fMLP, but Not LTB4, Activates PMN αβ₁β₂ Integrins

The findings presented above indicate that β₁ integrins, and specifically αβ₁β₂ integrins, mediate the qualitatively distinct effects of fMLP and LTB4 on PMN adhesion to, and migration through, fibrin gels. To determine whether fMLP and LTB4 differentially affect the activation of β₁ integrins we used mAb 15/7, which recognizes a confor-
mationally determined epitope on activated \( \beta_1 \) integrins (Bohnsack et al., 1995). PMN incubated for 30 min with fMLP exhibited a 10–22-fold increase in binding of mAb 15/7 (Fig. 5 J), compared with unstimulated PMN (Fig. 5 B), whereas PMN incubated for the same length of time with LTB4 (Fig. 5 F) showed little change over unstimulated PMN (Fig. 5 B) with respect to binding of mAb 15/7. Control experiments showed that surface expression of \( \beta_1 \) integrins was stimulated approximately twofold by LTB4 (Fig. 5 G), and approximately threefold by fMLP (Fig. 5 K), whereas \( \beta_2 \) integrin surface expression was stimulated approximately fivefold by LTB4 (Fig. 5 H) and approximately ninefold by fMLP (Fig. 5 L). Other studies showed that the extent of expression of the epitope for antibody 15/7 on \( \beta_1 \) integrins was dependent upon the dose of fMLP used to stimulate the PMN, and that \( 5 \times 10^{-6} \) M fMLP induced maximal expression of this epitope (not shown). In contrast, LTB4 concentrations 10–50-fold higher (i.e., \( 10^{-6} \) to \( 5 \times 10^{-6} \) M) than those used in the experiments described in Fig. 5 did not increase expression of the 15/7 epitope on \( \beta_1 \) integrins (data not shown).

### Effects of Antibodies against \( \beta_1 \) Integrins on Closeness of Apposition of fMLP- and LTB4-stimulated PMN to Fibrin

We have used exclusion of Rh-PEG 10 kD from zones of contact between chemoattractant-stimulated PMN and fibrin-coated surfaces as a measure of the closeness of apposition of PMN to the underlying substrate (Loike et al., 1995). Previously, we reported an inverse correlation between the formation of zones of close apposition between chemoattractant-stimulated PMN and fibrin gels and the capacity of PMN to migrate through these gels (see Fig. 7 in Loike et al., 1995). In the present experiments we used exclusion of Rh-PEG 10 kD to test whether antibodies and peptides that block \( \beta_1 \) integrins, and that facilitate migration of fMLP-stimulated PMN through fibrin gels (Figs. 2 and 3 A and Table I), affect the closeness of apposition of these cells to fibrin. Antibodies against the \( \beta \) chain of \( \beta_1 \) integrins, or against the \( \alpha_5 \) chain of \( \alpha_5 \beta_1 \) integrins (not shown), reduced the percentage of fMLP-stimulated PMN that excluded Rh-PEG 10 kD from zones of contact with fibrin from 80% to 20–30% (Fig. 6), and reduced the percentage of LTB4-stimulated PMN that excluded R-h-PEG 10 kD from these contact zones from 20% to <2% (Fig. 6).
rhodamine (Rh)-PEG 10 kD, and to inhibit PMN migration through fibrin (as measured by exclusion of FITC-dextran, 5 kD). For this experiment, PMN were incubated with or without antibodies against αβ1 integrins, allowed to adhere to fibrin-coated surfaces in medium containing PMA, and then were incubated with rhodamine-conjugated probe. Values are expressed as the percentage of adherent PMN that forms such zones. Note that Rh-PEG 3.5 kD stained the surfaces uniformly, confirming the presence of fibrin underneath all adherent PMN and showing that molecules of 3.5 kD penetrate zones of close apposition.

Table II. Effect of Antibodies against β1 or β2 Integrins on Formation of Zones of Close Apposition to Fibrin by PMA-stimulated PMN

| Additions                  | Percent of PMN forming zones of close apposition |
|----------------------------|-----------------------------------------------|
| None                       | 78 ± 6                                        |
| Anti-β1                    | 77 ± 3                                        |
| Anti-β2                    | 12 ± 4                                        |
| Anti-β1 Antibody (2 μg/ml) | 94 ± 2                                        |
| Anti-β2 Antibody (2 μg/ml) | 95 ± 1                                        |
| Anti-β1 Antibody (8 μg/ml) | 14 ± 5                                        |

5 × 10^5 PMN stimulated with PMA (300 ng/ml) in 30 μl PBSG-HSA were allowed to adhere to each fibrin- or fibrinogen-coated spot of multispot slides in the presence or absence of P4C10 anti-β1 integrin antibody (2 μg/ml) for 30 min at 37°C. The preparations were further incubated at room temperature for 30 min with either fluorescein-conjugated antifibrinogen IgG (Loike et al., 1995), Rh-PEG 10 kD, or Rh-PEG 3.5 kD (Loike et al., 1992, 1993, 1995) and examined by epifluorescence microscopy. A zone of close apposition is defined as a region between adherent PMN and the underlying matrix from which fluorophore-conjugated probe is excluded. Values are expressed as the percentage of adherent PMN that forms such zones. Note that Rh-PEG 3.5 kD stained the surfaces uniformly, confirming the presence of fibrin underneath all adherent PMN and showing that molecules of 3.5 kD penetrate zones of close apposition.

Discussion

The different effects observed with fMLP and LTB4 on PMN adhesion to and chemotaxis through fibrin gels appear to be a consequence of qualitative differences in the effects of these chemoattractants on the activity of β1 integrins. That is, fMLP activates β1 integrins (Fig. 5 and Table III), stimulates PMN to adhere closely to fibrin(ogen) (Fig. 6 and Table III; Loike et al., 1995), and inhibits PMN chemotaxis through fibrin gels (Fig. 2 and Table III; Loike et al., 1995). In contrast, LTB4 neither activates β1 integrins (Fig. 5 and Table III) nor induces PMN to adhere closely to fibrin(ogen) (Fig. 6 and Table III; Loike et al., 1995), and stimulates PMN to migrate through fibrin gels (Fig. 2 and Table III; Loike et al., 1995). To our knowledge, this is the first demonstration that signals initiated by two chemically distinct chemoattractants with their respective seven membrane spanning/heterotrimeric G protein-coupled receptors exert different effects on the activation state of a specific β1 integrin, and regulate PMN migration.

Fibrin(ogen)-containing Matrices Exert a Specific Effect

As shown in Fig. 2, fibrin(ogen) is unique among the matrix and plasma proteins tested in arresting the migration of fMLP-stimulated PMN. This is particularly notable in the case of fibronectin, a well-recognized ligand for α5β1 integrins. The failure of fibronectin to induce migration arrest suggests that fibrin(ogen) has heretofore unrecognized properties, independent of its ability to bind α5β1 integrins, that are important in its ability to cause migration arrest.

Relationship between Closeness of Apposition, Tightness of Adhesion, and Cell Migration

DiMilla et al. (1993) and Palecek et al. (1997) reported...
that smooth muscle cells migrate optimally on fibronectin-coated surfaces when their integrins bind to these surfaces at intermediate strengths. Weber et al. (1996) reported an inverse correlation between the strength of adhesion of chemokine-stimulated monocytes to surfaces coated with the 120-kD RGD-containing fibronectin fragment and the capacity of these cells to migrate across filters coated with this fibronectin fragment. The findings of Keller et al. (1979) and of Wilkinson et al. (1984), and those reported in Fig. 6, demonstrate an inverse correlation between closeness of apposition of PMN to surfaces coated with proteins that express ligands for PMN receptors and the ability of PMN to migrate on or through matrices containing these proteins. Thus, it seems likely that loose versus close apposition between cells and matrix protein-coated substrates reflects weak versus strong adhesion, respectively, between the cells and the substrate.

### PMA Bypasses $\beta_1$ Integrins in Stimulating PMN to Adhere Closely to Fibrin

Antibodies against $\beta_1$ integrins reduced adhesion, inhibited close apposition between PMA-stimulated PMN and fibrin (Table I), and blocked PMN migration through fibrin (data not shown). Antibodies against $\beta_1$ integrins had no effect on any of these parameters (Table I and data not shown). These results demonstrate that the interaction of activated $\beta_1$ integrins with fibrin is both required and sufficient for PMA-stimulated PMN to form zones of close apposition on fibrin (Table I), and that PMA bypasses the requirement for engagement of activated $\beta_1$ integrins by matrix proteins for PMN to form zones of close apposition on fibrin.

### Pathways by Which fMLP and LTB4 Activate $\beta_1$ and $\beta_2$ Integrins

Although the signal transduction pathways by which chemoattractants regulate PMN $\beta_1$ and $\beta_2$ integrins remain to be elucidated, our findings lead us to make three suggestions regarding the organization of these pathways.

First, antibodies that activate $\beta_1$ integrins do not promote adhesion of unstimulated PMN to fibrin, or inhibit LTB4-stimulated chemotaxis of PMN through fibrin gels (unpublished data). These results suggest that signals initiated by both fMLP receptors and activated $\beta_1$ integrins are required to inhibit chemotaxis of fMLP-stimulated PMN through fibrin gels.

Second, the finding that fMLP and PMA have similar effects on PMN adhesion to and migration through fibrin gels might suggest that the interaction of activated $\beta_2$ integrins of fMLP-stimulated PMN with fibrin activates protein kinase C, and that this is the mechanism by which fMLP signals $\beta_2$ integrins to bind closely to fibrin. However, Laudanna et al. (1996) reported that calphostin C, a protein kinase C inhibitor, blocks adhesion of PMA-stimulated, but not of fMLP-stimulated, mouse lymphocytes transfected with fMLP receptors, to VCA M-1-coated surfaces. (Adhesion of chemokine-stimulated lymphocytes to VCA M-1 is mediated by activated $\alpha_4 \beta_1$ integrins.) Laudanna et al. (1996) identified rho as a key participant in fMLP- and IL-8-mediated activation of $\alpha_4 \beta_1$ integrins in mouse lymphocytes. This finding suggests to us that rho acts downstream of $G_{\alpha_i}$ in activating $\beta_1$ integrins. The report of Caron and Hall (1998) that rho participates in coupling CR3 (CD11b/CD18) to the actin cytoskeleton suggests that rho also affects $\beta_2$ integrin-mediated functions. Whether PMN LTB4 receptors activate rho is unknown and should be investigated.

Third, binding of fMLP to its receptor activates $G_{\alpha_i}$ (Laudanna et al., 1996). The specific $G_{\alpha_i}$ activated by LTB4 in PMN has not been reported. Pertussis toxin, which inactivates $G_{\alpha_i}$, blocks most effects of LTB4 and of fMLP on human PMN. Thus, the finding that fMLP activates $\beta_1$ integrins (Fig. 5 J) while LTB4 does not (Fig. 5 F) suggests that binding of LTB4 to its receptor activates $G_{\alpha_i}$ subunits other than, or in addition to, $G_{\alpha_i}$ and that this difference in $G_{\alpha_i}$ subunit utilization is responsible for the divergent effects of fMLP and LTB4 on $\beta_1$ integrin activation (Fig. 5), and on closeness of PMN adhesion to fibrin (Fig. 6). Indeed, Arai and Charo (1996) have shown differential utilization of $G_{\alpha_i}$ subunits after MCP-1 or IL-8 stimulation of MCP-1 or IL-8 receptor transfected HEK 293 cells, and Yokomizo et al. (1997) have demonstrated that pertussis toxin treatment does not ablate Ca$^{2+}$ increases stimulated by LTB4 in LTB4 receptor-bearing CHO cells.

### Proposed Mechanisms by Which fMLP Inhibits PMN Chemotaxis through Fibrin Gels

Our studies suggest at least three distinct mechanisms by which fMLP could inhibit PMN migration through fibrin gels. First, the combined strengths of adhesion of activated $\beta_1$ and $\beta_2$ integrins to fibrin could be sufficient to immobilize PMN on fibrin. Our unpublished finding that antibodies that activate $\beta_1$ integrins do not inhibit migration of LTB4-stimulated PMN through fibrin gels casts doubt on this combined-strength-of-adhesion hypothesis as an ex-

---

**Table III. Summary of Results**

| Assay                  | mAb added: | fMLP | LTB4 |
|------------------------|------------|------|------|
|                        | None       | Anti-$\beta_1$ | Anti-$\beta_2$ | None       | Anti-$\beta_1$ | Anti-$\beta_2$ | None       |
| Adhesion to fibrin*    | >40%       | >40% | <10% | ~50%   | ~66%    | <10%    | ~5%        |

* Percent of control. About 40% and 60% of the added PMN adhered to the fibrin-coated surfaces in response to fMLP and LTB4, respectively. ND, not done; bkg, background.
planation for the inhibitory effect of fMLP on PMN chemotaxis through fibrin.

Second is the possibility that binding of fMLP or LTB4 to its cognate receptors directly and differentially activates β2 integrins for weak or strong adhesion, respectively. According to this hypothesis, fMLP-activated β2 integrins play no role in inhibiting chemotaxis of fMLP-stimulated PMN through fibrin. However, since activated β2 integrins mediate outside-in signaling, RGD peptides and antibodies against β3 integrins reverse fMLP's inhibitory effect on PMN migration through fibrin by stimulating β3 integrins to signal trans-dominant negative (Diaz-Gonzalez et al., 1996) effects on β3 integrins. A gainst this hypothesis are the findings that antibodies against the α6 chains of β3 integrins (Fig. 3), and antibodies that activate β3 integrins (unpublished data), do not reverse fMLP's inhibitory effect on PMN chemotaxis through fibrin.

Third, and we think most likely, is that the capacity of fMLP to promote close adhesion to, and to block migration through, fibrin gels is mediated by a cascade of signals (diagrammed in Fig. 7), in which the interaction of activated β2 integrins with the fibrin matrix causes trans-dominant activation of β2 integrins. This mechanism is consistent with previous studies (Pommier et al., 1983; Wright et al., 1984; Brown, 1992) showing that interaction of PMN or macrophages with RGD-containing matrix proteins activates α5β3 integrins for phagocytosis of C3bi-coated particles.

As shown in Fig. 7, we suggest that the interaction of LTB4 or fMLP with their respective PMN receptors generates a "common" signal that activates β2 integrins for loose adhesion to fibrin (Fig. 7 A and B, and D and E, respectively). In addition, we propose that fMLP receptors (Fig. 7 C) also signal activation of αβ2 integrins (Figs. 5 J and 7 E). We further suggest that binding of activated αβ2 integrins to fibrin matrices clusters these integrins, thereby generating an outside-in signal that activates β2 integrins (Fig. 7 F), for close apposition between PMN and fibrin-coated substrates (Fig. 7 G).

Close apposition reflects tight adhesion (Keller et al., 1979; Wilkinson et al., 1984; D’Milla et al., 1993; Palecek et al., 1997), presumably mediated by the coupling of β2 integrins to the cytoskeleton. We do not know whether tight adhesion causes, or is merely associated with, cessation of migration. In either case, PMN cease migrating (Figs. 2 A and 3 A, and Table I). We propose that antibodies and peptides that block the interaction of activated αβ2 integrins with fibrin (Figs. 2 and 3, and Table I) inhibit these outside-in signals, thereby blocking trans-dominant activation of β2 integrins for close apposition to fibrin (Fig. 6 and Table II) and allowing PMN to migrate through fibrin.

The interaction of LTB4 with its receptor also generates a signal that stimulates β2 integrins for loose apposition. However, LTB4 does not activate β1 integrins (Fig. 5 F). Therefore, these β2 integrins do not bind to the matrix, do not generate outside-in signals, and therefore do not initiate trans-dominant activation of β2 integrins for close apposition (Fig. 7 A-C), or cessation of migration.

What Characterizes the Sessile State?

Further work is needed to determine whether cessation of migration is merely a function of strong adhesion between PMN and fibrin or whether it reflects reorganization of the PMN cytoskeleton as observed by Dustin et al. (1997) in antigen-sensitized T lymphocytes. They found that these cells become immobilized when they encounter MHC class II molecules containing a peptide antigen recognized by the T lymphocytes’ antigen receptors. They identified changes in microtubule organization of these sessile T lymphocytes that distinguish them from their randomly migrating brethren. We suspect that PMN that adhere to fibrin after fMLP stimulation will exhibit similar changes in cytoskeletal organization.

Why Are There So Many Different Chemoattractants for PMN?

Our findings suggest that the availability of many different chemoattractants (e.g., fMLP, LTB4, IL-8, C5a, etc.) serves two complementary functions. First, they provide redundancy, thereby assuring that pathogenic microbes are detected rapidly by the innate immune system. Second, they reflect the need to direct PMN to different tissue sites and to prepare them for interactions with many different types of ligands.

Chemoattractant-encrypted Stop Signals Provide a Gradient-independent Mechanism for Leukocyte Accumulation at Specific Anatomic Sites

Our findings also suggest an alternative to the notion that leukocyte accumulation at a specific anatomic site in vivo requires the presence of a gradient of chemoattractant/chemokine emanating from that site. While there is no doubt that gradients of chemoattractants/chemokines are formed in vitro (Keller et al., 1979; Wilkinson et al., 1984; Huber et al., 1991; Campbell et al., 1996, 1997; Foxman et al., 1997; Palecek et al., 1997), they may be difficult to maintain in vivo in the face of the perturbing effects of muscular contraction and variations in blood and lymph flow.

Leukocytes in the vascular system begin to enter specific
tissue compartments when they encounter a chemotractant/chemokine. We suggest that once within this tissue compartment leukocytes migrate randomly in response to a relatively uniform concentration of matrix-bound chemotractant/chemokine. When in the course of this random walk they encounter extracellular matrix proteins or cells that express ligands for a specific activated β₂ integrin, they adhere strongly and become sessile. By regulating activation of specific receptors and adhesive strengths, concentrations of chemotractants/chemokines well below those required to saturate or desensitize chemotractant/chemokine receptors can mediate a stochastic process by which leukocytes accumulate at specific anatomic sites and form highly ordered structures (e.g., granulomas, germal centers). A corollary to this model, leukocytes accumulate at specific anatomic sites by a process that is similar in principle to the accumulation of flies on fly paper.

Foxman et al. (1997) showed that multiple chemotractants/chemokines can work in combination to elicit migration patterns that cannot be achieved by a single chemotractant/chemokine. The mechanisms we and they have described are complementary. These mechanisms are likely to be of special importance within tissue compartments where overlapping fields of chemotractants/chemokines/cytokines surely exist, and where cells migrate in stepwise fashion from one anatomic site to another (e.g., T cell movement in lymph nodes from T cell–rich paracortical zones to germinal centers; Garside et al., 1998), PM N accumulation at foci of bacterial infection, or of immune-complex deposition (Wilkinson et al., 1984). The essential point of the findings reported here is that by endowing leukocytes, and probably all migrating cells, with a modest number of receptors for different chemotractants, chemokines, and cytokines, nature has made optimal use of instructive and selective mechanisms to achieve a level of organizational specificity that would otherwise require substantially more genetic information.

We thank Drs. A.R. Horwitz and Sally Zigmond for helpful discussions, Eugene Butcher and Ellen Foxman for suggestions about the manuscript, Eric Brown for sharing unpublished data, and one of the reviewers for particularly thoughtful suggestions. This study was supported by National Institutes of Health grant AI20516, Bristol-Myers Squibb Research, and a generous gift of the late Samuel W. Rower.
