ABSTRACT

Aims. Stellar activity is a potentially important limitation to the detection of low-mass extrasolar planets with indirect methods (radial velocity, photometry, astrometry). In previous works, using the Sun as a proxy, we investigated the impact of stellar activity (spots, plages, convection) on the detectability of an Earth-mass planet in the habitable zone (HZ) of solar-type stars with radial velocity techniques. We here extend the detectability study to astrometry.

Methods. We used the sunspot and plages properties recorded over one solar cycle to infer the astrometric variations that a Sun-like star seen edge-on, 10 pc away, would exhibit, if covered by such spots/bright structures. We compare the signal to the one expected from the astrometric wobble (0.3 mas) of such a star surrounded by a one Earth-mass planet in the HZ. We also briefly investigate higher levels of activity.

Results. The activity-induced astrometric signal along the equatorial plane has an amplitude of typically less than 0.2 mas (rms = 0.07 mas), lower than the one expected from an Earth-mass planet at 1 AU. Hence, for this level of activity, the detectability is governed by the instrumental precision rather than the activity. We show that for instance a one Earth-mass planet at 1 AU would be detected with a monthly visit during less than five years and an instrumental precision of 0.8 mas. A level of activity five times higher would still allow this detection with a precision of 0.35 mas. We conclude that astrometry is an attractive approach to search for such planets around solar type stars with most levels of stellar activity.

Key words. planetary systems – stars: variables: general – Sun: activity – sunspots – Astrometry

1. Introduction:

Stellar activity is now recognized as a potentially strong limitation for the indirect detection of planets. Indeed, spots and bright structures (plages, network) produce brightness inhomogeneities at the stellar surface that affect the photometric, astrometric, and radial velocity (RV) signals. The RV signal is also affected by the inhibition of convection in the active area. The amplitude of the activity-related stellar noise depends on the activity pattern and intensity, which is related to the stellar properties (age, temperature, etc.). For young, active stars, or late-type stars, the signal may mimic that of a giant planet with periods of the order of the star rotational period. For less active, solar-type main-sequence stars, the noise is much lower, but can nevertheless affect the detection of terrestrial planets. In two recent papers, we investigated the impact of spots (Lagrange et al. 2010; hereafter Paper I), plages and convection (Meunier et al. 2010; hereafter Paper II) on the detectability of an Earth-mass planet located in the habitable zone (HZ) of the Sun, as seen edge-on and observed in RV or in photometry. To do so, we took into account all spots and plages recorded over one solar cycle. We showed that providing a very tight and long temporal sampling (typically twice a week over more than two orbital periods) and an RV precision in the 10 cm/s range, the photometric contribution of plages and spots should not prevent the RV detection of Earth-mass planets in the HZ. This is no longer true when convection is taken into account.

Here, we complete the previous work by estimating the astrometric signal produced by the same structures over the same solar cycle, and we compare it to the astrometric signal induced by an Earth-mass planet located at 1 AU from the Sun. We also compare this signal with the RV and photometric signals.

2. Data and results

2.1. Data

The data used to compute the astrometric signals are fully described in Paper II. In brief, they consist of all (20873) sunspot groups larger than 10 ppm of the solar hemisphere, provided by USAF/NOAA (http://www.ngdc.noaa.gov/stp/SOLAR/) and all (1803344) bright structures: plages (in active regions) and network structures (bright magnetic structures outside active regions) found from MDI/SOHO (Scherrer et al. 1995) magnetograms larger than 3 ppm, during the period between May 5, 1996 (JD 2450209) and October 7, 2007 (JD 2454380). The temperatures associated to these two types of structures was deduced from the comparison between the variations of the resulting irradiance and the observed ones (Froehlich & Lean 1998) during this period. Our temporal sampling is one day, with a few gaps, corresponding to a coverage of 86%.
Fig. 1. Temporal variations of the astrometric shifts along (top) and perpendicular to (bottom) the equator, caused by the combination of spots and bright structures. The Sun is supposed to be seen edge-on and located 10 pc away.

Fig. 2. Astrometric shift (deltax) as a function of time (top) and excursions of the photocenter (bottom) during a low-activity period (JD 2450335 to JD 2450365).

2.2. Astrometric temporal variations

For each date, we compute the position ($x$, $y$) of the Sun photocenter caused by the presence of these dark and bright structures, assuming it is seen edge-on, 10 pc away. The resulting shifts along and perpendicular to the equatorial plane are shown as a function of time in Fig. 1. We report in Table 1 the rms of the shifts during the entire cycle, as well as during the low and high activity periods, and the corresponding values for the RV and photometric signals.

Finally, we provide in Fig. 2 the temporal variations of the astrometric shift along the equator as well as the global excursion of the photocenter during a short 30-day period during the low-activity phase. The astrometric signal, if measured precisely enough, allows the determination of the star rotation period. The same is true for the RV and photometric signals. The astrometric signal would furthermore provide additional and unique information. In Fig. 2, we see that the structure at the origin of the observed variations is located in the southern hemisphere of the star, and it moves from east to west, i.e. from the left to the right in the lower panel of Fig. 2. Therefore, the astrometric signal provides the means, within one rotation period, to determine the direction of the star’s rotational axis in the plane of the sky. Note that this assumes that we know by photometry or RV measurements if the perturbing structures are hotter or cooler than the photosphere and requires a very good astrometric precision. Moreover, one needs to isolate and monitor one single structure, which means that only periods of low activity can provide this information (indeed, during more active periods, the contributions of all individual structures mix).

2.3. Relation between RV, photometric, and astrometric signals

The astrometric variations along the equatorial plane are well correlated with the RV signal caused by spots and plages (see top panel of Fig. 3). For a single spot, the ratio between the shift and the RV depends on the star’s properties ($v \sin i$) and is almost independent of the spot properties. The correlation found here shows that this property remains when taking several spots/structures into account. The slope of the RV variations (in m/s) to the shifts (in μas) is 5, which is compatible with the value expected from a single spot. Once convection is taken into account in the RV computation, however, there is no correlation any longer between the astrometric shift in $x$ and the RV variations (see Fig. 3). This difference of behaviour between the “no-convection” and “convection” cases could in principle be used to estimate the level of convection, if any, that is associated to the star.

Finally, no correlation is found between the relative photometric variations and the astrometric shifts (either the $\Delta x$ or the shift-to-centre). This is not surprising because the photometric variations marginally depend on the spot/plage locations, conversely to the astrometric shifts.
We finally explore different levels of activity. We found that an instrumental precision similar to that expected for the NEAT instrument for a five hour-long visit of a G2 star located 10 pc away (0.35 μas) will easily allow the detection even for stars five times more active than the Sun (we conservatively assume that such a star will produce shifts five times higher than the Sun)\(^1\). This is illustrated in Fig. 5 where we show the periodograms of the shift along the equatorial plane (same sampling as before) during the low- and high-activity periods. Given Lockwood et al. (2007) relation between the relative photometric variations and the Ca H & K line strength index log(R’HK), and given the log(R’HK) for the Sun (between \(\log R’HK \approx -4.85\) and \(\log R’HK \approx -5.0\) respectively during the high- and low-activity phases), this corresponds to a log(R’HK) smaller than \(-4.25\). Most active stars fall into this regime. Indeed, among the 385 Hipparcos stars closer than 20 pc with a known R’HK, only eight have log(R’HK) \(\geq 2\). A detailed study of these stars is presented in section 3.1.

\(^1\) This value corresponds to the precision that NEAT will provide in such an observing sequence. In practice, each visit will be longer (up to about five hours) to ensure a better precision (precision is proportional to \(\sqrt{t_{\text{obs}}/2}\)).

\(^2\) In practice, a level of activity five times higher will probably induce shifts smaller than 5 times the shifts, as statistically, there will be more chances that the effects of structures located on a given side of the hemisphere be balanced by that of structures on the opposite side.

### 3. Discussion

#### 3.1. Planet detection in astrometry

We see in Fig. 1 that the activity-induced shifts are most of the time smaller than 0.2 μas, i.e. smaller than the amplitude of the shifts induced by an Earth-mass planet at 1 AU (0.33 μas along the equatorial plane and 0 μas perpendicular to the equator). These values agree with the estimates of Makarov et al. (2010).

The rms of the equatorial shift over the entire cycle is about five times smaller than the amplitude of the Earth signal, and four times smaller during high activity. This means that the Sun activity would not prevent the detection of an Earth-like planet located in the HZ, provided the precision of the data allows for these measurements. This is illustrated in Fig. 4, where we show the periodogram of the astrometric shifts along the equatorial plane once a one Earth-mass planet has been added (no noise). In this example, we use a limited amount of data instead of the whole set of data, in order to be closer to a real case. The chosen temporal sampling is of one month\(^1\) five days over 50 months, which is typical of the strategy adopted for the NEAT instrument recently proposed to ESA (Léger 2010), dedicated to a systematic astrometric search for exo-Earths in the HZ of nearby stars.

We then explored different instrumental noises. An example is given in the lower panel of Fig. 4 where we assume a noise of 0.8 μas\(^1\). The temporal sampling is the same as before. The planet is still detectable. However, now the correlation seen in the previous section between the astrometric shift along the equatorial plane and the RV variations is not any longer present. This is because the instrumental noise exceeds the activity-induced noise. The consequence is that if we take the instrumental noise into account, it will not be possible with this level of activity to estimate the level of convection using the astrometric and RV data.

We finally explore different levels of activity. We found that an instrumental precision similar to that expected for the NEAT instrument for a five hour-long visit of a G2 star located 10 pc away (0.35 μas) will easily allow the detection even for stars five times more active than the Sun. This is illustrated in Fig. 5 where we show the periodograms of the shift along the equatorial plane (same sampling as before) during the low- and high-activity periods. Given Lockwood et al. (2007) relation between the relative photometric variations and the Ca H & K line strength index log(R’HK), and given the log(R’HK) for the Sun (between \(\log R’HK \approx -4.85\) and \(\log R’HK \approx -5.0\) respectively during the high- and low-activity phases), this corresponds to a log(R’HK) smaller than \(-4.25\). Most active stars fall into this regime. Indeed, among the 385 Hipparcos stars closer than 20 pc with a known R’HK, only eight have log(R’HK) \(\geq -4.2\) (see Fig. 6; Maldonado et al. 2010).

So far we assumed that the angle of the planet orbit (supposedly identical to the equatorial plane) is known. For real observations though, this information will not be known a priori and

### Table 1. Measured rms for the shifts, RV and photometry caused by the spots and bright structures.

| Period | rms(ΔX) | rms(ΔY) | rms(RV) | rms(RV) | rms(TSI) |
|-------|---------|---------|---------|---------|----------|
|       | without conv. | with conv. |            |          |          |
| all   | 0.07    | 0.05    | 0.33    | 2.4     | 3.6 × 10⁻⁴ |
| high1 | 0.09    | 0.06    | 0.42    | 1.42    | 4.5 × 10⁻⁴ |
| high2 | 0.08    | 0.05    | 0.37    | 1.62    | 3.9 × 10⁻⁴ |
| low   | 0.02    | 0.01    | 0.08    | 0.44    | 1.2 × 10⁻⁴ |

**Notes.** Shifts in \(x\) and \(y\) are in μas, RV are in m/s. RV and photometry rms are taken from Paper II. The entire cycle (referred as “all”) to as well as low- and high-activity periods are considered. The low-activity period is from July 1, 1996 (JD 2450266) to April 1, 1997 (JD 2450540), and the first considered high-activity period (referred to as “high1”) is from February 1, 2000 (JD 2451576) to November 1, 2000 (JD 2451850). Both correspond to the low- and high-activity 9-month periods considered in Paper II. We also consider a longer (923 days) activity period (referred to as “high2”), from JD 2451577 to JD 2452500.

![Fig. 4. Periodograms of the shift along the equatorial plane of the Sun viewed edge-on and surrounded by a one Earth-mass planet at 1AU, and observed once a month approximately, for 50 months. From top to bottom: 1) low-activity period, no instrumental noise; 2) high-activity period, no instrumental noise; 3) low-activity period, 0.8 μas rms instrumental noise; 4) high-activity period, 0.8 μas rms instrumental noise.](image)
The situation is then different from the RV data, because the rms of the RV caused by spots and bright structures only (i.e., convection not taken into account) during the entire cycle, the low-activity period, and the high-activity period respectively are three, one and four times larger than the amplitude of the Earth RV signal (see Table 1). When we include convection, the corresponding ratios become 24, 4, and 14, respectively. Therefore, the RV detection limit is set by the stellar activity (and mainly by convection effects) rather than by the instrumental precision (provided precisions of 10 cm/s are available).

To prepare and accompany a space astrometric mission dedicated to Earth-mass planet detection, previous RV or photometric monitoring would certainly be very much appreciated. In particular, RV measurements are very powerful to derive the properties of the star’s activity. They are indeed more powerful than astrometry, because the rms of the activity-induced RV variations is much larger than the instrumental precision (conversely to astrometry). Previous long-term RV monitoring can allow the identification of the presence of larger bodies in the system and characterize them (note that lower precision astrometric monitoring can also do this). During the astrometric measurements, simultaneous RV observations with a precision of about 10 cm/s would provide detailed information on the actual activity of the star and will help the analysis of the astrometric data.
