ABSTRACT

Evidence is emerging that obesity-associated cardiovascular disorders (CVD) show variations across regions and ethnicities. However, it is unclear if there are distinctive patterns of abdominal obesity contributing to an increased CVD risk in South Asians. Also, potential underlying mechanistic pathways of such unique patterns are not comprehensively reported in South Asians. This review sets out to examine both. A comprehensive database search strategy was undertaken, namely, PubMed, Embase and Cochrane Library, applying specific search terms for potentially relevant published literature in English language. Grey literature, including scientific meeting abstracts, expert consultations, text books and government/non-government publications were also retrieved. South Asians have 3-5% higher body fat than whites, at any given body mass index. Additional distinctive features, such as South Asian phenotype, low adipokine production, lower lean body mass, ethno-specific socio-cultural and economic factors, were considered as potential contributors to an early age-onset of obesity-linked CVD risk in South Asians. Proven cost-effective anti-obesity strategies, including the development of ethno-specific clinical risk assessment tools, should be adopted early in the life-course to prevent premature CVD deaths and morbidity in South Asians.

Key words: Abdominal obesity, cardiovascular risk, cardiovascular diseases, diabetes mellitus, South Asians

INTRODUCTION

Increased health risks of obesity have been documented for centuries in Charaka Samhita\(^1\) and writings attributed to Hippocrates.\(^2\) Such observations are no less relevant now. Evidence is emerging that obesity-associated illnesses, specifically cardiovascular disorders (CVD) show variations across regions and ethnicities.\(^3,4\) One of the strongest phenomena in support of such observations is the recent redefinition of the body-mass-index (BMI) criteria, to specific populations, for example, the Asia-Pacific criterion for obesity.\(^5\) In this review, distinct patterns in obesity, mainly abdominal obesity, and its associated illnesses are discussed from a South Asian perspective. South Asians comprise individuals who belong to heterogeneous ethnicities and trace their origin from various countries in the Indian subcontinent (India, Pakistan, Nepal Sri Lanka and Bangladesh). There are two main focus areas of this review. First, what are the distinctive features of adult obesity in South Asians compared to Caucasian populations? Such an approach might help identify the uniqueness of clinical patterns of obesity-related illnesses in the South Asians and also help towards better clinical diagnosis and tailored management. Secondly, the underlying mechanistic pathways that contribute to such distinct patterns among the South Asians. This second...
aspect is vital for adopting a strategic approach to prevent and control obesity-related disease burden among the South Asians. In addition, this review discusses related topics, such as the need for new and revised cut-off points of BMI for specific ethnicities, the burden of obesity in specific population sub-groups, and main differences underlying abdominal obesity compared to general obesity.

DEFINITIONS

Obesity, is defined as a body fat content of more than 20% in average adult males and over 30% in females. However, obese individuals vary in the amount of excess fat that they store, the regional distribution of that fat within the body, and the related health consequences differ noticeably amongst these obese persons. It is therefore essential to make a distinction between those at augmented risk as a result of abdominal obesity from those with generalized obesity. Even though most epidemiological studies have only used BMI as a predictor of disease, there is substantiation that subjects with abdominal obesity, as assessed by measurement of waist circumference or waist-hip ratio, are at a greater risk of cardio metabolic risk, independently of risk associated with a raised BMI. Further, waist circumference beyond 90 cm in males and over 80 cm in females is an effectual clinical predictor of the metabolic risk like other clinical, biochemical and imaging variables. Such clinico-epidemiological observations are clearly important to redefine the occurrence of obesity-associated cardiovascular risks in a population where both obesity and CVD are recent phenomena. South Asians, in particular, have shown a different pattern of cardiovascular risks, both, in indigenous populations, and also those who migrated to the West.

MATERIALS AND METHODS

This review attempts a comprehensive database search strategy more akin to a systematic review approach; however, falls short of the scientific rigor involved in a systematic review. Nevertheless, the evidence drawn should add to the existing body of literature showing similar observations and conclusions. We abstracted the most significant published literature on the electronic databases, namely, Pub Med, Embase and the Cochrane Library applying specific search terms such as “South Asians”, “Asian Indians”, “obesity”, “overweight”, “cardiovascular risk factors”, “childhood obesity”; cardiovascular disorders - “CVD”; Coronary heart disease - “CHD”; “physical inactivity”; “metabolic syndrome”; “ethnicity” etc. We have also gone through articles unpublished on Pub Med; abstracts of conference/meetings; consulting authors/experts in the field; text books; and, publications of governmental/non-governmental organization. Articles only in English language were considered.

Globalization, epidemiological transition and obesity

Recent data of mounting burden of noncommunicable diseases synchronizing with globalization can be understood in the context of epidemiological, nutritional, demographic and socioeconomic transition across the globe. It has been hypothesized that obesity and type-2 diabetes had their lineage in a natural choice of early humans, favoring a “thrifty genotype” which enabled very well-organized storage of energy during periods of food abundance. Similarly, the ‘thrifty phenotype’ explains how low-birth-weight babies, who have been exposed to a chronic energy-deprived state, accumulate energy stores and go on to develop type-2 diabetes in adulthood. These genetic or phenotypic adaptations that were supportive in times of famine, have become detrimental with increasing nutritional availability and decreasing physical activity due to modern lifestyle.

Overweight and obesity in South Asians

Though South Asians have a very high prevalence of abdominal obesity, there is paucity of country wide accurate data and statistics related to this. Obesity in childhood and adolescence is attaining an alarming and epidemic proportion in India with about 15–20% of the population being affected. Similarly, about 30-65% of adult urban Indians are either overweight, obese or have abdominal obesity. Though the prevalence of obesity in South Asians is lower than whites, blacks and Hispanics, the health risks related with obesity crop up at a lower BMI in South Asians. These observations put

---

**Figure 1:** Thrifty genotype and epidemiological transition, modern lifestyle-metabolic stress with thrifty genes
forth the fact that the current World Health Organization (WHO) criteria to define overweight and obesity may not be suitable for Asian populace in general, and South Asians in particular.\[5,27\] Thus, a new criteria to define overweight and obesity in the Asia-Pacific and South Asian Region has been proposed.\[24,30\] The BMI and waist circumferences included in this criteria for the Asians has been\[9\] summarized in Table 1.

**World Health Organization Asia Pacific criteria for obesity**

On an average, in adult males the desirable body fat content is about 15-20%, and in females it is higher at about 25-30%.\[8\] Women have more fat than men for a given BMI. An analogous situation is seen for Asians as compared to whites and blacks. Asian populations have 3% to 5% higher body fat than others at an identical BMI.\[8\] Similarly, for a given amount of body fat, the BMI is 2 to 3 units lower in Asians than in whites. This observable fact is ascribed to the smaller body frame of Asians. Hence, the usual cut-points of obesity may not be suitable for Asians in general, and South Asians in particular.\[8\] The WHO recommends different cut off points for obesity in Asians.\[3\] A BMI more than 25 is considered obese for Asians in variation to 30 for other populations.\[8\] Furthermore, blacks have a lower body fat and different metabolic abnormalities for a given BMI. The optimum BMI appears to be below 23 for Asians, 23 to 25 for whites and 23 to 30 for blacks.\[8\] However, existing data does not essentially specify a clear BMI cut-off point for all Asians for overweight or obesity.\[27\]

**General obesity versus abdominal obesity**

Even as the relative importance of general and abdominal obesity is still debated, abdominal obesity is particularly considered of the atherogenic variety of adiposity, because it appears to promote a cluster of atherogenic risk factors associated with insulin resistance.\[29,30\] Abdominal obesity as represented by the waist circumference or the waist-hip ratio, has been shown to be a strong predictor of CHD, independent of the general level of obesity, although the BMI also influences CHD risk.\[33\] Furthermore, the markers of obesity, namely, BMI, waist size and waist hip ratio have a positive relationship with major cardiovascular risk factors like hypertension, metabolic diseases like diabetes; while, the waist hip ratio also correlates with dyslipidemia.\[32\]

Abdominal obesity is more common amongst South Asians than general adiposity, which is in contrast to whites, who have only a slightly higher rate of abdominal adiposity, and blacks who actually have a lower rate of abdominal obesity than general obesity.\[8,14\] Abdominal adiposity accumulates in three places: (i) subcutaneous fat, (ii) retro-peritoneal fat, and (iii) visceral fat. However, the visceral fat is considered to be most atherogenic, diabetogenic and hypertensiogenic fat depot of the human body.\[14\] Visceral fat is particularly deleterious because of its anatomical location and the resultant increased supply of free fatty acids to the liver via portal venous drainage.\[14\]

**Specific features of South Asian thin-fat phenotype**

‘Thin fat’ phenotype or muscle thin but adipose body composition is defined as a relatively low body mass index but increased total, subcutaneous and central (truncal and abdominal) body fat.\[33,34\] These features appear to be present from birth as Indian neonates tend to have increased body fat compared to their Caucasians despite lower birth weights.\[33,35\] These unique features led to the coining of the term ‘Thin-Fat phenotype’\[33\] or ‘Asian Indian Phenotype’.\[35\]

- Excess body fat: South Asians have higher percentage of body fat for a given BMI as compared to Caucasians and Blacks.\[8,14\]
- Abdominal obesity: Is seen with increased prevalence in South Asians even amongst those who have a BMI < 25 kg/m\(^2\).\[8,14\]
- Truncal subcutaneous fat: It is a particular distinctive feature and an important correlate of insulin resistance in this ethnic group.\[8,14\]
- Metabolic obesity: This can lead to numerous metabolic derangements like insulin resistance, dyslipidemias and hyperglycemia in conjunction with proinflammatory and prothrombotic factors even though they are non-obese by usual BMI values.\[23,36\]

| Classification | BMI (kg/m\(^2\)) | Risk of Co-morbidities | Waist circumference |
|---------------|-----------------|------------------------|---------------------|
| Underweight   | < 18.5          | Low (but increased risk of other clinical problems) | < 80 cm (men) < 80 cm (women) |
| Normal range  | 18.5 – 22.9     | Average                | ≥ 80 cm (men) ≥ 80 cm (women) |
| Overweight    | ≥ 23            | Increased              |                     |
| At risk       | 23 – 24.9       | Increased              |                     |
| Obese I       | 25 – 29.9       | Moderate               |                     |
| Obese II      | ≥ 30            | Severe                 |                     |

Pathophysiological effects of abdominal adiposity and increased cardiovascular risk in South Asians

For a better understanding of the clinico-epidemiological observations around obesity-associated cardiovascular risks, an insight into the underlying pathogenesis is useful. It is now well established that the insulin resistant, dyslipidemic, proinflammatory and prothrombotic state of abdominal obesity has been implicated as an important contributor in the pathogenesis of glucose intolerance and atherosclerotic CVD. Obesity involves uneven increases in the amount of adipose tissue relative to other tissues, and adipose tissue free fatty acids (FFA) turnover is also increased and the inhibition of lipolysis by insulin is decreased. The adipose tissue is the source of proinflammatory adipokines like tumor necrosis factor-alpha, interleukin-6, leptin, plasminogen activator inhibitor-1, angiotensiongen, resistin and C-reactive protein (CRP) that may play a role in metabolic and cardiovascular complications of obesity. It is also the source of anti-inflammatory and antiatherosclerotic adipokines i.e. Adiponectin. The same are depicted in the flow chart [Figure 2].

Increased vascular risk observed in South Asians may be attributed to altered adipokine production or action. Further, derangements in the adiponectin - insulin sensitivity axis may be an important biomarker linking visceral adiposity to atherogenesis in South Asians. Insulin resistance, impaired fibrinolysis and endothelial dysfunction also occur as a result of lower Adiponectin. These lower levels of Adiponectin also predispose them to increased susceptibility to vascular and diabetic risk. Further, they have higher plasma concentrations of leptin, an adipose tissue metabolite and nonesterified free fatty acids. Further, Leptin receptor gene polymorphism has been shown to have a role in obesity and Type 2 Diabetes mellitus. Hence, there is likelihood of unique anthropometric, biochemical and genetic risk factors that cause for an increased cardiometabolic risk in South Asians.

Determinants of obesity and cardiovascular disorders in South Asians

Role of body composition, Frame size / proportions
Evidence is emerging that proportion of fat free mass varies between populace of diverse ethnicities/racial backgrounds. Body compositions of Asians in general and south Asians in particular, have consistently revealed a lower lean mass and a higher proportion of body fat than Caucasians. Much of the ethnic variation in the relationship between BMI and body fatness is explained by differing body proportions and frame sizes.

Role of ethnicity
The first clue that people of Asian origin were more prone to visceral obesity and CVD at low levels of BMI came from studies involving migrants from South Asia. As stated earlier, Asians have 3 to 5% higher body fat than whites, at any given BMI. Among Asians who have the same BMI, Chinese have the lowest percentage of body fat, while Indians have the highest. At a given waist size, Asians have greater body fat and metabolic abnormalities.

Rate of weight gain and duration
Evidence is emerging about importance of weight gain and duration as vital determinants of CVD risk than BMI alone. Further, the association of weight gain, duration of adiposity and CVD risk is of importance in South Asians as they are showing rapid weight gain in their populace due to changing lifestyle. However, the most alarming aspect of epidemiological transition in South Asia is the rapid increase in number of children who are overweight and affected by obesity.

Rapid changes in diet and physical activity
As a consequence of globalization, increased urbanization and mechanization, dietary habits are changing and physical activity levels are reducing, resulting in a rapid increase

Figure 2: Pathophysiological effects of abdominal adiposity
in the mean body weight of the population in the South Asian region. Further, South Asians are changing from the consumption of traditional frugal diets to energy rich imbalanced foods along with sedentary lifestyle.

**Low birth weight and fetal under nutrition**

Widespread prevalence of maternal malnutrition in South Asia resulting in low birth weight and fetal under nutrition, can have lasting undesirable effects on cardiometabolic risk factors in growing children. Further as under nutrition coexists with over nutrition in South Asia, focusing on efforts to improve the nutrition during pregnancy, while simultaneously avoiding excessive weight gain needs consideration.

**Socioeconomic factors**

There is reversal of social gradient in cardiovascular risk factors in South Asians, and the disease burden shifts towards lower socioeconomic strata. Further, the obstacles to control non communicable diseases in South Asia include extreme poverty and inadequate health infrastructure.

**Sociocultural factors**

Lack of disease awareness, lack of health-seeking behavior, delayed diagnosis, language barriers, and religious and sociocultural factors are important in South Asia. Illiteracy, ignorance and blind beliefs amongst women lead to maternal malnutrition, and mothers tend to feed their children with ghee, butter and other fats for growth and strength. Moreover women in certain communities are not allowed to leave their homes, thereby leading to physical inactivity.

**Prevention and Control**

Prevention and control of noncommunicable diseases is a global priority for the WHO and obesity management is an important part of the strategy being employed. The prevalence of obesity in children and adolescents is rapidly growing as well. The presence of obesity at this age appears to program adult obesity and CVD. The importance of early intervention for obesity in childhood, for future prevention of adult CVD, need to be emphasized. The proper risk stratification for adolescents could direct clinicians in identifying overweight youth who are at an increased risk of developing pre-diabetes, diabetes, or CVD, and lead to a timely intervention. In this regard, life style changes that are beneficial for obesity related cardiovascular risk factors are listed in Table 2.

Obesity management should incorporate a broad range of long term strategies ranging from prevention, weight maintenance and management of obesity related comorbidities to weight loss. It also necessitates both population approach and an individual approach. The population based effort should focus on the community, including schools and media; and, the individual approach should consist of a multidisciplinary strategy involving physicians, exercise specialists, dieticians, nurses and other health care personnel. Further, it is imperative to stress that strategies should be cost effective, culturally sensitive, adoptable to local practices, and messages conveyed should be straightforward and implementable with meager health resources, omnipresent illiteracy, blind beliefs and ignorance in South Asian nations.

**CONCLUSION**

South Asians have a distinct obesity pattern in the form of increased fat mass and low lean mass than Whites for the same level of BMI. More importantly, the review indicates that the early onset of CVD risk among South Asians may be related to insulin resistant, dyslipidemic, proinflammatory, prothrombotic state of abdominal obesity. However, an altered adipokine production can also be linked to increased vascular risk, as observed among the South Asians. Evidence is emerging to suggest that there is a likelihood of unique anthropometric, biochemical and genetic risk factors for cardiometabolic risk in South Asians. Thus, a distinct clinical diagnostic tool for

| Risk factor                      | Increase                                                                 | Decrease                                                                 |
|---------------------------------|--------------------------------------------------------------------------|--------------------------------------------------------------------------|
| Physical inactivity             | 30-60 minutes of moderate intensity of activity daily                     | Sedentary life style                                                     |
| Atherogenic diet                | Intake of fruits and vegetables                                           | Energy dense calorie intake                                             |
| Hypertriglyceridemia            | Physical activity                                                        | Weight by reducing calorie intake                                       |
| Low-HDL                         | Monounsaturated fat intake                                               | Weight by reducing calorie intake                                       |
| Hypertension                    | Physical activity                                                        | Weight by reducing calorie intake                                       |
| Glucose abnormalities           | Low-fat dairy products                                                   | Weight by reducing calorie intake                                       |
|                                 | 30-60 minutes of moderate intensity of activity daily                     | Weight by reducing calorie intake                                       |
|                                 | Intake of fruits and vegetables                                           | Weight by reducing calorie intake                                       |
South Asians, as well as a tailored obesity management is warranted.

Moreover socio-cultural factors, economic factors, low birth weight status, and ethnicity, as an independent non-modifiable risk factor, can all contribute to increased obesity-associated CVD risk in South Asians. Such ethnic-specific determinants of obesity are crucial for prevention and control of obesity-associated illness in South Asians. In addition, the application of Asia-Pacific BMI cut-off point rather than the universal WHO BMI cut-off levels would be more scientific and accurate for estimating obesity-associated CVD risk burden in South Asians. Thus, we would like to conclude on a rather cautious note that anti-obesity management should be encouraged earlier in the life trajectory of South Asian populations. Though the escalating number of childhood obesity and overweight cases could be a challenge for the governments and healthcare providers, it would certainly contribute to positive health gains in the foreseeable future. Nevertheless, cost-effective interventions in reducing weight gain should be undertaken in local populations in real-life situations for further evidence in support of reducing CVD risk, not only in South Asians but also in similar populations elsewhere.
