Abstract

Although ovarian cancer is the most lethal of gynecologic malignancies, wide variation in outcome following conventional therapy continues to exist. The presence of tumor-infiltrating regulatory T cells (Tregs) has a role in outcome of this disease, and a growing body of data supports the existence of inherited prognostic factors. However, the role of inherited variants in genes encoding Treg-related immune molecules has not been fully explored. We analyzed expression quantitative trait loci (eQTL) and sequence-based tagging single nucleotide polymorphisms (tagSNPs) for 54 genes associated with Tregs in 3,662 invasive ovarian cancer cases. With adjustment for known prognostic factors, suggestive results were observed among rarer histological subtypes; poorer survival was associated with minor alleles at SNPs in RGS1 (clear cell, rs10921202, \( p = 2.7 \times 10^{-6} \)), LRRC32 and TNFRSF18/TNFRSF4 (mucinous, rs3781699, \( p = 4.5 \times 10^{-6} \), and rs3753348, \( p = 9.0 \times 10^{-6} \), respectively), and CD80 (endometrioid, rs13071247, \( p = 8.0 \times 10^{-8} \)). For the latter, correlation coefficients in CD80 rs13071247 genotype association with CD80 tumor RNA expression \( (p = 0.006) \). An additional eQTL SNP in CD80 was associated with shorter survival \( (rs7804190, p = 8.1 \times 10^{-5}) \) among cases combined. As the products of these genes are known to affect induction, trafficking, or immunosuppressive function of Tregs, these results suggest the need for follow-up phenotypic studies.

Introduction

Ovarian cancer is the fifth leading cause of cancer death among women in the United States [1]. Five-year overall survival is approximately 45%, and, even with modern surgical and chemotherapeutic strategies, most cases with advanced disease relapse and succumb to the disease [2,3]. Rare germline BRCA1 or BRCA2 mutations confer improved survival [4]. Common inherited variants could also influence outcome; genome-wide association studies (GWAS) are underway, but have yet to find
survival-associated loci [5]. Consideration of novel biological pathways using in-depth analysis of variation in candidate genes holds promise for the identification of prognostic genetic factors.

Several studies demonstrate the importance of the immune system in ovarian cancer outcome. For example, in one report, cases with evidence of CD3+ T cell tumor infiltration (approximately one-half of the cases studied) showed improved progression-free and overall survival [6]. Subsequent studies have refined our understanding of tumor-infiltrating T cells, including one showing that CD8+ T lymphocytes are the primary sub-population of T cells associated with better survival [7]. Along with the finding that tumor antigen-specific T cell responses can be detected in cases, these results suggest that anti-tumor immunity is elicited against ovarian cancers and impacts the clinical course of the disease [8]. Despite this generation of an immune response, however, anti-tumor immunity is counterbalanced by an immune suppressive microenvironment [9]. Of immune suppressive mechanisms, CD4+ regulatory T cells (Tregs) are a primary means of immune evasion in ovarian cancers; these are CD4+ T lineage cells whose primary function is immune regulation [10]. In collaboration with others, we first suggested a role of tumor-infiltrating Tregs in ovarian cancer pathogenesis, reporting higher levels of CD4+ Tregs, measured with immunofluorescence, among cases with poorer survival [11]. Subsequent work supports the importance of CD4+ Tregs in ovarian cancer pathogenesis and outcome [7,12]. For example, the presence of CD4+ Tregs appears to influence the anti-tumor activity of tumor-infiltrating cytotoxic CD8+ T cells [7]. CD4+ Tregs block both adaptive and innate immune effectors by cell contact mechanisms as well as by soluble mediators [13,14]. Soluble mediators of suppression commonly associated with CD4+ Tregs include IL-10 and TGF-β, both of which block T cell proliferation and cell-mediated immunity [15,16,17]. Other cell surface molecules implicated in suppressing the immune response include B7-H1 (CD274), GITR (TNFRSF18), LAG-3, CTLA-4, and surface-bound TGF-β [18,19,20].

Because of the importance of CD4+ Tregs and a role for inherited factors in outcome, we assessed whether common inherited variation related to CD4+ Treg-related genes was associated with ovarian cancer outcome following standard of care therapy. Specifically, we assessed 54 genes key to the induction, trafficking, or immunosuppressive functions of CD4+ Tregs. Utilizing data from a novel candidate gene study combined with existing data, we studied polymorphisms that have been shown to affect the expression of or to tag inherited variation in these genes. Variants associated with outcome in multiple study populations could shed light on immunosuppressive mechanisms in ovarian cancer.

Materials and Methods

Ethics Statement

Protocols were approved by the appropriate institutional review boards (Mayo Clinic Institutional Review Board, Roswell Park Cancer Institute Institutional Review Boards, Duke University Institutional Review Boards, National Cancer Institute Institutional Review Boards, Moffitt Cancer Center Institutional Review Boards) or ethics panel (Royal Marsden Hospital ethics panel, University of Cambridge ethics panel, University College London ethics panel). All participants gave written informed consent.

Candidate Gene SNP Array

Fifty-four genes of key relevance to the biology of Tregs (ACVR2B, AGTR1, CCL11, CCL17, CCL19, CCL2, CCL20, CCL22, CCL3, CCL4, CCL5, CCR4, CCR6, CCR7, CCR8, CD274, CD46, CD80, CD86, CXCL10, CXCL13, CXCR5, DUSP4, EGR2, GPR133, IDO1, IKZF2, IKZF4, IL10RB, IL15RA, IL2RB, IL6ST, IL9, INHBA, INHBB, IRF4, ITGAEM, KLF10, LAG3, LRRC92, MDHIC, NRPI, PDCD1, PLAG1, PRNP, RGS1, RG16, SH2BGRK2, SLC22A2, SMAD3, SOCS2, TNFRSF18, TNFRSF4, and TNFRSF9) were chosen for study (Table S1). The relevance of these genes was established from a PubMed [21] database search which revealed published information that either directly showed or suggested a role for the respective gene products in the induction, immune suppressive function, or trafficking of Tregs. Eighty-five genes associated with ovarian cancer outcome following standard of care therapy. Specifically, we assessed 54 genes key to the inherited variation related to CD4+ in ovarian cancer outcome following standard of care therapy. Specifically, we assessed 54 genes key to the immortalization of cancer cells. These genes include those that are associated with CD4+ cells whose primary function is immune regulation [10]. In collaboration with others, we first suggested a role of tumor-infiltrating Tregs in ovarian cancer pathogenesis, reporting higher levels of CD4+ Tregs, measured with immunofluorescence, among cases with poorer survival [11]. Subsequent work supports the importance of CD4+ Tregs in ovarian cancer pathogenesis and outcome [7,12]. For example, the presence of CD4+ Tregs appears to influence the anti-tumor activity of tumor-infiltrating cytotoxic CD8+ T cells [7]. CD4+ Tregs block both adaptive and innate immune effectors by cell contact mechanisms as well as by soluble mediators [13,14]. Soluble mediators of suppression commonly associated with CD4+ Tregs include IL-10 and TGF-β, both of which block T cell proliferation and cell-mediated immunity [15,16,17]. Other cell surface molecules implicated in suppressing the immune response include B7-H1 (CD274), GITR (TNFRSF18), LAG-3, CTLA-4, and surface-bound TGF-β [18,19,20].

Because of the importance of CD4+ Tregs and a role for inherited factors in outcome, we assessed whether common inherited variation related to CD4+ Treg-related genes was associated with ovarian cancer outcome following standard of care therapy. Specifically, we assessed 54 genes key to the induction, trafficking, or immunosuppressive functions of CD4+ Tregs. Utilizing data from a novel candidate gene study combined with existing data, we studied polymorphisms that have been shown to affect the expression of or to tag inherited variation in these genes. Variants associated with outcome in multiple study populations could shed light on immunosuppressive mechanisms in ovarian cancer.

Candidate Gene Study Participants and Genotyping

Cases genotyped on the Treg custom SNP array included women with pathologically-confirmed invasive primary epithelial ovarian, peritoneal, or fallopian tube cancer enrolled at the Mayo Clinic and Roswell Park Cancer Institute (RPCI). Mayo Clinic cases (N = 905) were ascertained between December 1999 and November 2010 into the Mayo Clinic Ovarian Cancer Case-Control Study (MAY) or the Mayo Clinic Case-Only Ovarian Cancer Study (MAC) and included women aged 20 years or above who were enrolled within a week of diagnosis (median time from diagnosis to recruitment was zero days). RPCI cases (N = 167) were residents of Western Pennsylvania, Eastern Ohio, or Western New York, aged 25 years or above and ascertained between January 2004 and May 2009 within six months of diagnosis through Roswell Park Cancer Institute’s Divisions of Gynecological Surgery and Oncology. These cases were enrolled with a median time from diagnosis to recruitment of 80 days. At both sites, DNA was extracted from 10 to 15 mL fresh peripheral blood (using Gentra AutoPure LS Purging salt out methodology at Mayo Clinic and FlexiGene DNA Kit methodology at RPCI), stored at −80°C, and bar-coded to ensure accurate processing. A total of 1,072 participants were genotyped using a custom Illumina Goldengate BeadArray Assay along with 24 duplicates and 24 HapMap CEU replicates (8 trios). Concordance among study duplicates was 99.998%, no SNPs had unresolved replicate or Mendelian errors, and the mean genotype call rate was 99.88%. Samples with genotyping failure (N = 32) or call rate <97% (N = 11) were excluded as well as samples found to be incorrectly plated (N = 1) or from cases deemed ineligible due to non-epithelial disease (N = 5), borderline tumor behavior (N = 34), or enrollment more than one year prior to diagnosis (N = 5). SNPs with genotyping failure (N = 162), call rate <95% (N = 19), or HWE <0.0001 and poor clustering (N = 15) were excluded. Thus, analyses were based on 994 cases and 1,340 SNPs.

Genome-Wide Association Study

We also analyzed data from the Follow-up of Ovarian Cancer Genetic Association and Interaction Studies (FOCI) collaboration

Ovarian Cancer Survival and Treg SNPs
which is part of the National Cancer Institute GAME-ON Post-GWAS initiative and is described elsewhere [26,27]. In brief, participants were 2,167 self-reported white invasive ovarian cancer cases enrolled in the North Carolina Ovarian Cancer Study (NCO), the NCI Ovarian Case-Control Study in Poland (POL), the Royal Marsden Cancer Study (RMH), the UK Studies of Epidemiology and Risk Factors in Cancer Heredity Ovarian Cancer Study (SEA), the Tampa Bay Ovarian Cancer Study (TBO), and the UK Familial Ovarian Cancer Registry and the Cancer Study (SEA). Among 570 endometrioid ovarian cancer cases, minor alleles at an intronic CD80 tagSNP rs13071247 were associated with a 73% increased risk of mortality (p = 8.0 × 10^{-4}, Table 2). In addition, analysis of all cases regardless of histology suggested that an eQTL SNP for CD80 (rs7804190) was associated with 14% shorter survival time (p = 8.0 × 10^{-4}).

Among 272 mucinous ovarian cancers, minor alleles at four SNPs in leucine rich repeat containing 32 (LRRC32) were associated with greater than two-fold poorer survival. Three of these SNPs (rs3781669, rs197155, rs3781701) were highly correlated (r^2 = 0.97), thus only one of these is presented in Table 2 (rs3781669 p = 4.5 × 10^{-4}). A fourth SNP, LRRC32 SNP rs7944357, was only modestly correlated with this three-SNP cluster (r^2 ≤ 0.26), yet was also associated with survival among cases with mucinous ovarian cancer (p = 8.3 × 10^{-4}). One other SNP rs3753348 showed association with a more than three-fold risk with survival in mucinous ovarian cancer (Table 2); this SNP resides in the 5 kb region between tumor necrosis factor receptor superfamily members 4 and 18 (TNFRSF4 and TNFRSF18) on chromosome 1.

Among 507 endometrioid ovarian cancer cases, minor alleles at an intronic CD80 tagSNP rs13071247 were associated with a 73% increased risk of mortality (p = 8.0 × 10^{-4}, Table 2). In addition, analysis of all cases regardless of histology suggested that an eQTL SNP for CD80 (rs7804190) was associated with 14% shorter survival time (p = 8.0 × 10^{-4}). The rs7804190 eQTL, which resides intronic to MAD1 mitotic arrest deficient-like 1 (yeast) (MAD1L1), is of interest because genotype has been found to correlate with expression of CD80 (p = 6.0 × 10^{-5}), as well as polymerase (DNA directed), beta (POLB), proline-serine-threonine phosphatase interacting protein 2 (PSTPIP2), and KIAA1128 (p < 10^{-5}) in lymphoblastoid cell lines [22]. Of note, no SNPs were associated with survival following serous ovarian cancer (p > 0.001), the most common and most lethal histologic subtype. Tests for interaction revealed no site-specific heterogeneity of association for any of the SNPs in Table 2 (p > 0.05 for each).

To explore potential mechanisms of the observed SNPs associated with ovarian cancer survival, we examined tumor RNA expression data on 54 Mayo Clinic cases and correlated expression with genotype at the most suggestive survival-associated SNPs described above. At CD80 rs13071247, an association was observed such that heterozygotes and minor allele homozygotes (AC and CC genotypes) had slightly increased tumor expression (median fold change = 1.04 on the raw scale, 0.06 on the log2 scale) than cases with AA genotype (p = 0.006; Figure 1). No other associations between genotype and tumor RNA expression were observed at p < 0.05.

**Discussion**

Previous studies support an important role for Tregs in ovarian cancer which appear to foster an immune suppressive microenvironment. Here, we analyzed ovarian cancer survival in relation to inherited Treg genotypes using a combination of customized genotyping and integration of existing genotypes from a collaborating GWAS. While no SNPs yielded suggestive results among the more common serous cases, poorer survival was associated with minor alleles at SNPs in RS1 (clear cell), LRRC32 and TNFRSF18/TNFRSF4 (mucinous), and CD80 (endometrioid). For the latter, additional data support a CD80 genotype
association with CD80 tumor RNA expression. Combined analysis of multiple independent datasets provides greater statistical power than separate discovery and replication analyses [29]; thus, we used this study design and examined the possibility of heterogeneity of results across studies. As no statistically significant heterogeneity across studies was observed, our inference is based on this combined, most powerful approach. It is worth noting that we examined a relatively large number of SNPs across 54 Treg-associated genes and across different histologic subtypes, and therefore we acknowledge that multiple testing issues may exist; some of our highlighted results could indeed be false positive associations. The fact that the genes examined were chosen based on an a priori role in ovarian cancer and that we concentrated only on SNP associations with p-values less than 0.001 lessens, but does not entirely eliminate, this possibility. Nonetheless, this work highlights particular Treg-related genes of interest.

CD80 has been extensively studied for its role in immune responses, yet no focused analysis of SNPs and ovarian cancer outcome has been reported, to our knowledge. It acts as a ligand for both CD28 and CTLA4, leading to proliferation and anergy in

Table 1. Distributions of Ovarian Cancer Clinical Characteristics by Study.

| Case Group | Vital status at last follow up | Age at diagnosis | Histology | Stage | Grade | Self-reported race |
|------------|-------------------------------|------------------|-----------|-------|-------|-------------------|
| MAY+MAC (N = 873) | Alive 450 (52%) | <50 years 126 (14%) | Serous 638 (79%) | Stage I/II 176 (20%) | Low grade 116 (14%) | White 767 (98%) |
| RPCI (N = 121) | Deceased 423 (48%) | 50–69 years 484 (55%) | Endometrioid 106 (13%) | Stage III/IV 692 (80%) | High grade 724 (86%) | Non-white 13 (2%) |
| NCO (N = 492) | Alive 264 (54%) | 70+ years 263 (30%) | Clear cell 46 (6%) | Unknown 5 | Low grade 33 | Unknown 93 |
| POL (N = 210) | Deceased 228 (46%) | | Mucinous 22 (3%) | | | 1 |

| UKO+UKR (N = 527) | | | | | | 0 |
| Total (N = 3,665) | Alive 719 (66%) | Deceased 368 (34%) | Serous 502 (53%) | Stage I/II 512 (61%) | Low grade 442 (55%) | White 1,087 (100%)
| | | 26 % | Endometrioid 201 (21%) | Stage III/IV 326 (39%) | High grade 365 (45%) | Non-white 2 |
| | | 12% | Clear cell 109 (12%) | Unknown 155 (19%) | | |
| | | 5% | Mucinous 129 (14%) | Unknown 247 (33%) | | |
| | | 2% | Other/unknown 47 (4%) | Unknown 1,195 (38%) | | |

Table 2. Regulatory T Cell SNPs Associated with Overall Survival (p<0.001).

| Case Group | Gene | SNP | MAF | Location | HR (95% CI) | p-value |
|------------|------|-----|-----|----------|-------------|---------|
| Clear Cell (N = 217) | RGS1 | rs10921202 | 0.07 | Intron | 2.93 (1.77–4.84) | 2.7×10⁻⁵ |
| Mucinous (N = 272) | LRRC32 | rs3781699 | 0.35 | 3’ UTR | 2.32 (1.45–3.71) | 4.5×10⁻⁴ |
| | TNRFSF4/TNRFSF18 | rs7964357 | 0.44 | Intron | 2.04 (1.34–3.10) | 8.3×10⁻⁴ |
| Endometrioid (N = 570) | CD80 | rs13071247 | 0.14 | Intron | 1.73 (1.26–2.39) | 8.0×10⁻⁴ |
| All Cases (N = 3,655) | CD80 | rs7804190 | 0.37 | MAD1L1 | 1.14 (1.06–1.23) | 8.1×10⁻⁴ |

Adjusted for study site (MAY+MAC, RPCI, POL, UKO+UKR, TBO, NCO, RMH, SEA), age at diagnosis (<50 years, 50–69 years, >70 years), tumor stage (I or II, III or IV, unknown), race (white, non-white, unknown), and tumor grade (low, high, unknown); linkage disequilibrium reduced to r²<0.95; MAF, minor allele frequency.

doi:10.1371/journal.pone.0053903.t001

doi:10.1371/journal.pone.0053903.t002
naive T cells, respectively [30,31,32]. CTLA4 is constitutively expressed in Tregs, where it is important in suppressing immune responses through a variety of proposed mechanisms, including activation of the indoleamine-2,3-dioxygenase pathway in dendritic cells (DCs) and inhibition of interactions between activated T cells and DCs [33,34,35]. We observed that an intronic tagging CD80 SNP was associated with poorer survival of endometrioid cases and with increased tumor CD80 expression, and, among all cases, we observed that an eQTL SNP on another chromosome which associated with CD80 lymphocyte expression was also associated with poorer survival. Altogether, these data suggest that CD80 expression may be in part driven by inherited factors and may lead to increased immune suppression and poorer outcome.

Of interest to clear cell ovarian cancer, the gene product of RGS1, RGS1 or BL34, is a member of the RGS protein family whose members are involved in regulation of G-protein signaling. Specifically, they are GTPase-activating proteins that limit the duration of G-protein signaling [36,37]. Lymphocyte migration to chemotactic signals are mediated by G-protein signals and previous studies have found that Tregs do not respond as well to chemokine signaling as naive T cells [38]. Furthermore, RGS1 is more highly expressed in Tregs and expression is inversely correlated with migration [38]. Interestingly, RGS1 gene expression is increased in activated Tregs, and this is mediated by binding of the Treg transcription factor FOXP3 to the RGS1 gene [39]. Associations of RGS1 SNPs have also been observed in numerous T cell-mediated autoimmune diseases, including type 1 diabetes, celiac disease, and multiple sclerosis [40,41,42,43]. Based on these prior studies, it is tempting to speculate that genetically determined RGS1 levels may regulate Treg infiltration into clear cell ovarian cancers and thus contribute to outcome.

A SNP of possible relevance to mucinous disease is in LRRC32 which encodes GARP, a transmembrane protein expressed specifically on naturally occurring activated Tregs, but not resting Tregs [44,45]. GARP has been shown to be a receptor for inactive, latency-associated peptide (LAP) bound TGF-β [46,47]. GARP does not induce activation of latent TGF-β; however, it may function in infectious tolerance, converting FOXP3+ cells to suppressive FOXP3+ cells [46,49]. Additionally, GARP is part of a positive feedback loop with FOXP3 in Tregs, which are known to maintain a suppressive tumor microenvironment and prevent an effective immunological response [45]. Our finding of poorer survival among mucinous cases with minor alleles at an LRRC32 SNP suggests that these cases may have increased immune suppression.

We report an association between risk of death due to mucinous ovarian cancer and a SNP in a gene cluster containing TNFRSF18 and TNFRSF4. TNFRSF18 encodes GITR, a co-stimulatory molecule present constitutively on Treg cells and upregulated on naive T cells after stimulation. Reports are conflicting as to the role of GITR, as it has been reported both to increase [49,50] and to abolish the suppressive function of Tregs [51,52]. While the specific mechanism of GITR action remains controversial, it is clear that it modulates Tregs. TNFRSF4 encodes OX40 (CD134), and signaling through OX40 reduces the ability of Tregs to act as suppressor cells by decreasing expression of FOXP3 [53,54]. Reduced FOXP3 results in decreased miR155 and a subsequent increase in SOCS1 (suppressor of cytokine signaling 1). SOCS1 is a component of a negative feedback loop.
for IL-2 signaling cascade; increased expression of SOCS1 results in a need for increased IL-2 levels for survival of Tregs [55]. Thus, OX40 signaling in Tregs can modulate suppressor functions both by decreasing their effector function and by requiring higher amounts of IL-2 for continued survival and activation. The integration of SNP associated with overall survival in cases with mucinous ovarian cancer may act through either a GITR or OX40 mechanism. Dissecting the role of the germline variants may help to identify mechanisms that could explain why the immune system is not able to mount an effective response to ovarian cancers.

In conclusion, our analysis of 3,662 invasive ovarian cancer cases suggests that inherited variants related to Tregs are associated with ovarian cancer outcome in a subtype-specific manner, even after adjustment for known prognostic features. Our findings underscore the importance of subtype-specific analyses in clinical and epidemiological studies of ovarian cancer, given the established disease heterogeneity, with each histologic subtype expressing different patterns of genetic, epidemiologic and clinical characteristics [reviewed by Karst and Drapkin [56]]. Future work should include examination of additional study populations, immunological studies, and correlation of inherited variants with other tumor features, such as levels of Treg infiltration.
