Recently, the discovery of organometallic halide perovskites provides promising routes for fabricating optoelectronic devices with low cost and high performance. Previous experimental studies of MAPbI$_3$ optoelectronic devices, such as photodetectors and solar cells, are normally based on polycrystalline films. In this work, a high-performance planar-type photodetector fabricated on the (100) facet of a MAPbI$_3$ single crystal is proposed. We demonstrate that MAPbI$_3$ photodetector based on single crystal can perform much better than that on polycrystalline-film counterpart. The low trap density of MAPbI$_3$ single crystal accounts for the higher carrier mobility and longer carrier diffusion length, resulted in a significant performance increasement of MAPbI$_3$ photodetector. Compared with similar planar-type photodetectors based on MAPbI$_3$ polycrystalline film, our MAPbI$_3$ single crystal photodetector showed excellent performance with good stability and durability, broader response spectrum to near-infrared region, about 10$^2$ times higher responsivity and EQE, and approximately 10$^3$ times faster response speed. These results may pave the way for exploiting high-performance perovskites photodetectors based on single crystal.

Photodetectors which can convert light signals into electrical ones instantaneously have sparked wide interests because of their important applications, such as video imaging, optical communication, environmental monitoring, and biomedical sensing$^{1-4}$. The recent discovery of solution-processed organometallic halide perovskites (MAPbX$_3$, X = I, Br, Cl) provides promising routes for fabricating optoelectronic devices with low cost and high performance$^{5-8}$. Among these organometallic halide perovskites, methylammonium lead triiodide (MAPbI$_3$) has been the spotlight owing to its appropriate direct band gap$^9$, large absorption coefficient$^6$, long-range balanced electron- and hole-transport lengths$^{10,11}$, and high charge carrier mobilities$^{11-13}$. Park and Graetzel reported the strong photocurrent multiplications of the MaPbI$_3$ which enables its application as a photodetector$^{14}$. Until now, several significant efforts to fabricate novel high-performance MAPbI$_3$ photodetectors, such as perovskite-graphene hybrid photodetector$^{15}$, perovskite nanowires-based photodetectors$^{16,17}$, and highly stable perovskite photodetector$^{18}$, etc. have been made. The performances of several recently reported pure MAPbI$_3$ based photodetectors are listed in Supplementary Table S1. It can be seen that photodetectors based on organometallic halide perovskite MAPbI$_3$ demonstrate the advantages of high-responsivity, high quantum efficiency, and fast response speed at low driving voltage.

In general, these MAPbI$_3$-based photodetectors can be classified into two structural types: planar-type and vertical-type. Xie et al.$^{19}$ reported the first MAPbI$_3$ photodetector, which is a typical planar-type one. The MAPbI$_3$ polycrystalline film photodetector (MPFP) was found sensitive to a broadband response

spectral response ranging from the ultraviolet to near-infrared light, showing a high photo-responsivity (R) of 3.49 A W⁻¹, 0.0367 A W⁻¹, and an external quantum efficiency (EQE) of 1.19 × 10⁻⁶, 5.84% at 365 nm and 780 nm under a bias voltage of 3 V, respectively. Dong et al.²⁰ demonstrated a vertical-type highly efficient photodetector based on MAPbI₃ polycrystalline film, showing a broadband response spectrum that ranges from the 300 nm (UV) to 800 nm (NIR). The gain of their MAPbI₃ photodetectors was influenced by the MAPbI₃ layer thickness and achieved the maximum when the thickness was between 360 and 410 nm. A very high responsivity of 242 A W⁻¹ at low bias (~1 V) was attained by this vertical-type photodetector. Compared with the planar-type photodetectors, the elaborate vertical-type devices require more patterning steps for fabrication. On account of the inevitable non-radiative defects incurred by these steps at the edges of the layers, the device performance will be detrimentally affected.²¹ However, as a matter of fact, the vertical-type MPFPs could perform much better than the planar-type ones, demonstrating higher gain and quicker response. The reason, on the one hand, lies in the fact that the electrode spacing plays an important role in making these differences. As for planar-type MPFPs, the spacing is typically tens of micrometers long, while that of the vertical-type MPFPs is usually tens of hundreds of nanometers long. The length of the former is influenced by the bridging-gap on the substrate,²² and that of the latter is determined by the film thickness. As a result, the electrons and holes in the planar-type devices have to move much longer than those in the vertical-type ones to the electrodes.²²

On the other hand, numerous defects and extensive disorders in MAPbI₃ polycrystalline film antagonize the charge migration process. All the problems mentioned above hinder the MAPbI₃ photodetectors from utilizing intrinsic properties to achieve the optimal performance, especially for planar-type devices.

To improve the performance of MAPbI₃ photodetectors, it is necessary to reduce the defect density by increasing the crystalline quality of MAPbI₃ film, or perhaps more directly, to fabricate photodetectors based on single crystals. MAPbI₃. Recently, single crystals of perovskites MAPbI₃ have shown remarkably low trap density and excellent charge transport properties. Shi et al.²³ observed low trap-state density on the order of 10⁶ to 10⁷ per cubic centimeter and long carrier diffusion lengths exceeding 10 micrometers in MAPbX₃ single crystals. Dong et al.²⁴ reported that the diffusion lengths in MAPbI₃ single crystals could exceed 175 μm under 1 sun illumination and exceed 3 mm under weak light for both electrons and holes, which far exceeds the value measured from polycrystalline MAPbI₃ films (typically smaller than 1 μm).²⁰,²¹ These results potentially suggest that the optoelectronic device based on single-crystalline perovskite could perform much better than that on the polycrystalline counterpart. Thus, remarkable performance improvement is expected in the planar-type perovskite photodetector regardless of the micron-long electrode spacing. Additionally, degradation of MAPbI₃ has always been a notorious drawback for their real application in optoelectronic devices. The MAPbI₃ polycrystalline film device without modification usually wears off very quickly when exposed to ambient air.²⁵,²⁶ Many efforts have been made to enhance the durability of perovskite polycrystalline film devices, such as the smart and simple way of spin-coating with a CYTOP layer on perovskite film.²⁷ Nevertheless, the MAPbI₃ single crystal may provide better stability, since it averts the prejudicial effects of grain boundaries and a large number of surface defects in polycrystalline film.

In this work we propose a planar-type photodetector fabricated on the (100) facet of an MAPbI₃ single crystal. We demonstrate that MAPbI₃ single crystal photodetector (MSCP) can perform much better than the devices based on polycrystalline film. Although it was fabricated as the simplest device without elaborate electrode decoration, the MSCP demonstrated high responsivity of 953 A W⁻¹ and EQE of 2.22 × 10⁻⁶ at 1 V applied voltage when illuminated with the weakest detectable 532 nm light of 2.12 nW cm⁻². When exposed to a relative strong light at 1 mW cm⁻², compared with the similar planar-type photodetector based on polycrystalline (R: 0.0197 A W⁻¹, EQE: 4.59%), the MSCP showed about 100 times higher responsivity of 2.55 A W⁻¹ and EQE of 5.95 × 10⁹%. Additionally, the MSCP showed excellent performance with good stability and durability, broader response spectrum to near-infrared region and approximately three orders of magnitude faster response speed.

Results
Centimeter-sized MAPbI₃ bulk single crystals were grown via a bottom-seeded solution growth (BSSG) method. Seed crystals were first prepared according to Poglitsch and Weber's method.²⁷ Some deposits appeared in the bottom of the flask and tended to adhere to the surface of the growing seed during the cooling process. The formation of many nucleuses obviously antagonizes the growth of large bulk single crystal of MAPbI₃. To eliminate such a negative effect, a platinum wire was utilized to fix and prop the seed crystal up to separate the seed crystal from contacting the bottom of the flask. A clean bulk single crystal was obtained after lowering the temperature of the growth solution from 373 K to 330 K over the course of 15 days. A MAPbI₃ single crystal with the dimension of 12 mm × 12 mm × 7 mm is shown in Fig. 1a with the oriented natural facets labelled. X-ray single crystal structural analyses were performed at room temperature and the space group was confirmed as I4/mcm (140), which was consistent with the report in 1987.²⁷ For MAPbI₃ single crystal, three-dimensional Pb-I links form the integral structural framework, and the MA⁺ ion is in a cage made by four PbI₆ octahedra. Details of structural description is presented in the supplementary material (Supplementary Table S2 and Figure S1–2). A comparison of XRD patterns of the rhombic and the parallelogram natural crystallographic facets of a MAPbI₃ single crystal is presented in Fig. 1b, where the calculated polycrystalline XRD pattern was provided as a
The inset in Fig. 1b shows the detail when 2 theta is around 20 degree. The obvious difference between the two patterns is a direct guidance to identify the rhombic and the parallelogram natural crystallographic facets as (100) and (112) facets, respectively. Sharp and symmetric peak pattern of each facet indicates the good quality of the MAPbI₃ single crystal. As presented in Fig. 1c, the structural drawing of (100) facet of MAPbI₃ crystal suggests the modeled transporting tunnel for photo-generated electrons and holes. Optical properties were measured on a (100)-cut MAPbI₃ single crystal plate with 1 mm in thickness (Supplementary Figure S3). It was found that the MAPbI₃ single crystal presents a broad band absorption extending to 840 nm (Fig. 1d), implying potentiality of applying this material in near-infrared optoelectronic devices. For the semiconductor material, the optical absorption is closely related to the energy gap between the conduction and the valence band. Through first principle computation and experimental study, MAPbI₃ exhibits the optical features of a semiconductor with direct band gap.

Supplementary Figure S4 shows the transmission spectrum of as-prepared MAPbI₃ single crystal plate at room temperature. The transmission intensity maintains high from 887 nm to 1200 nm and gradually decreases below 887 nm with a cut-off wavelength of 813 nm. As presented in the inset of Supplementary Figure S4, the optical band gap of MAPbI₃ single crystal was deduced through extrapolation method and calculated to be 1.48 eV, which is consistent with Tao and co-workers' report but lower than 1.5 ~ 1.6 eV as reported previously in thin polycrystalline film. Remarkably, optical absorption characterization based on a single crystal clarifies the lower but more accurate band gap evaluation for MAPbI₃ material, eliminating the impacts of other factors such as grain boundaries, substrates and scaffolds. To conclude, MAPbI₃ single crystal possesses a broader absorption band. Therefore, it is more advantageous to act as light-harvester or photodetector than polycrystalline film. In addition, Raman vibrational spectrum of MAPbI₃ single crystal in the low-frequency region at room temperature was collected and assigned (Supplementary Figure S5).
As schematically illustrated in Fig. 2a, a pair of interdigitated Au-film electrodes were deposited on the (100) facet of MAPbI₃ single crystal to form a planar-type photodetector. The bridging-gap of electrodes width was about 20 μm, while the effective illuminated area of MAPbI₃ single crystal was about 1.19 × 10⁻⁷ m² (Supplementary Figure S6). To study the photo-electric convertibility of our device, I~V curves under different illumination power were measured by using a 532 nm laser as the light source with the power densities varying from 0.11 to 3.22 mW cm⁻² (Fig. 2b). All measurements were performed in air at room temperature. The dark current was plotted as a reference, which was as low as 11 nA at 4 V bias. When exposed to light, the photocurrent increased dramatically. The I-V curves show a nonlinear and asymmetrical behavior, indicating that a Schottky contact between MAPbI₃ single crystal and Au electrodes was formed. It is observed that the rising rate of photocurrent increases first and then decreases, implying that it may undergo a saturation effect of photocurrent with bias voltage increasing. This phenomenon may arise from the built-in electric fields effect. The charging and discharging processes by switching power supply of 1 V and 0 V under 0.79 mW cm⁻² illumination were recorded in Supplementary Figure S7, and the existence of the built-in electric fields was expounded in the supplementary material. A high photocurrent of 11.2 μA was achieved at −3 V bias under 3.22 mW cm⁻² illumination.

Two crucial parameters for photodetectors, i.e. spectral responsivity (R) and EQE, were measured and calculated. The spectral responsivity, defined as the ratio of photocurrent to incident light intensity, can be expressed by:

\[
R = \frac{I_{ph}}{P_0 \cdot S}
\]  

(1)

where \(I_{ph}\) is the difference between the illuminated current and dark current \((I_{ph} = I_{illuminated} - I_{dark})\), \(P_0\) is the irradiance power density, and \(S\) is the effective illuminated area. It is also very important for a photodetector to have a high conversion rate from photons to electrons/holes, or high EQE, which can be expressed by the equation:

\[
EQE = \frac{R \cdot h c}{e \lambda}
\]  

(2)

where \(R\) is the spectral responsivity, \(h\) represents the Planck’s constant, \(c\) stands for the velocity of light, \(e\) is the electronic charge and \(\lambda\) is the wavelength of incident light.

To illustrate the superiority of single crystal MAPbI₃, MPFP devices were fabricated as reference for comparisons. Considering that the value of responsivity and EQE strongly depends on the applied voltage, light power and device structure, identical interdigitated Au-film electrodes was deposited on the surface of MAPbI₃ thin-film, structurally the same as MSCPs on (100) crystal facet, as shown in Supplementary Figure S8. Furthermore, the irradiance power-dependent photoresponse characteristics, such as R and EQE values for both MSCP and MPFP were evaluated at a fixed 1 V bias, as shown in Fig. 3a,b. One can see that both the R and EQE decreased as the irradiance increased, thus the highest values for R and EQE could be measured at the lowest detectable irradiance power. It is worth pointing out that for each device of MSCP and MPFP, the irradiance power densities were intentionally selected ranging from the lowest detectable value to about 10⁴ mW cm⁻². The MSCP was found to achieve better...
detection thresholds than MPFP. The lowest detectable irradiance power density was evaluated to be 2.12 nW cm\(^{-2}\) for the former, under which the highest R value of 953 A W\(^{-1}\) and an EQE of \(2.22 \times 10^5\%\) were achieved. Below 120 nW cm\(^{-2}\), the photocurrent signal of MPFP could no longer be observed as it was covered by the noise and dark current. Therefore the highest R and EQE values for MPFP at 1 V voltage were calculated to be 0.28 A W\(^{-1}\) and 64.64%, respectively. Moreover, under illumination with the same irradiance power density of 1 mW cm\(^{-2}\), the R values for MSCP and MPFP were estimated to be 2.55 A W\(^{-1}\) and 0.0197 A W\(^{-1}\), while the corresponding EQE values were calculated to be \(5.95 \times 10^2\%\) and 4.59%, respectively. Clearly the results demonstrated that the responsivity and EQE for MSCP are more than two orders of magnitude higher than those of MPFP.

At the same voltage, the photocurrent increased gradually as their radiance intensity increased. The relationship between the photocurrent and the irradiance power density can be fitted by the power law:

\[ I_{ph} = a \cdot P_0^x \]  

where \(I_{ph}\) represents photocurrent, \(a\) is constant, \(P_0\) represents irradiance power density, and \(x\) is the exponential term. At a bias of 1 V, the irradiance-dependent photocurrent was plotted and fitted by \(I_{ph} \sim P_0^{0.632}\) (Supplementary Figure S9). Moreover, linear dynamic range (LDR, typically quoted in dB), another figure-of-merit for photodetectors, was evaluated for MSCP. As depicted in Supplementary Figure S10, under illumination at 532 nm, the LDR for our MSCP was calculated to be 76 dB.

Figure 3. A comparison of irradiance power-dependent photoresponse characteristics, responsivity R (a) and external quantum efficiency EQE (b), for as-fabricated MSCP and MPFP. The light source was a 532 nm laser and all measurements were performed at a fixed bias of 1 V. The irradiance power densities for each device are in a range from the lowest detectable value to about 10^2 mW cm^{-2}.

Figure 4. Wavelength-dependent properties of as-fabricated MSCP irradiated by monochromatic light from Xe lamp. Spectral responsivity R (a) and external quantum efficiency EQE (b) of MAPbI\(_3\) single crystal photodetector at different wavelengths from 275 nm to 790 nm at various bias from 1 V to 5 V.
Next, the spectral photoresponse was measured with a 300 W Xe lamp equipped with a manual monochromator. The MSCP shows a broadband detection characteristic from 275 nm to 790 nm, with a high $R$ of around $10^4$ A W$^{-1}$ and EQE of over $10^3$% even at a relatively low bias voltage of 1 V (Fig. 4). The corresponding irradiance power density ($P_0$) at each measured wavelength were depicted in Supplementary Figure S11. It is notable that the $R$ and EQE of our MSCPs sustained high till the near-infrared wavelength of 790 nm, while that of MPFPs decreased sharply from 725 to 800 nm. These results indicate that MSCP possesses a broader spectral detectivity than MPFP. It should be noted that the characterization of $R$ and EQE over 790 nm are not successful due to the limitation of the monochromator used. Nevertheless, a broadband detection cut-off towards 840 nm is expected, considering the absorption characteristics of the MAPbI$_3$ single crystal (Fig. 1d). The MSCP presented a maximum EQE value of $1.55 \times 10^4$% at 5 V with $375 \times 10^{-3}$ mW cm$^{-2}$ irradiance, and the corresponding responsivity was calculated to be 47.1 A W$^{-1}$. Additionally, both the $R$ and the EQE decreased when the voltage varied from 5 V to 1 V.

Figure 5 shows the photo-switching characteristics of the MSCP at different applied voltages of 0.5, 1, 2, and 3 V, respectively, and excellent repetition of photocurrent was observed under photo-switching conditions. A peak photocurrent of 7.6 $\mu$A was achieved at 3 V bias, exhibiting a good photocurrent on/off ratio of 224. A fast response speed to light switch is much desired for the purpose of photodetector application. To further demonstrate the response speed of the MSCP, the high speed features of the device were measured by an optical chopper of 500 Hz under 0.79 mW cm$^{-2}$ illumination using a 532 nm laser (Fig. 6a). Defined as the time taken from the initial photocurrent to 90% increase and decrease, the rise and decay times for our MSCP were calculated. The rise time was 74 $\mu$s after triggering and the decay time was 58 $\mu$s after irradiation terminated. Similarly, as a comparison, by utilizing a optical

Figure 5. Time-dependent photocurrent response of MSCP. Photocurrent decay and rise at different voltages of 0.5, 1, 2, and 3 V with on-and-off light (532 nm, 1.75 mW cm$^{-2}$).

Figure 6. A comparison of transient photocurrent characteristics for as-fabricated MSCP and MPFP. (a) Transient photocurrent response for the MSCP with on-and-off light with a switching frequency of 500 Hz. (b) Transient photocurrent response for the MPFP with a switching frequency of 33 Hz. The measurements were conducted under 0.79 mW cm$^{-2}$ illumination using a 532 nm laser.
chopper of 33 Hz the rise and decay times for MPFP were measured to be 52 and 36 ms (Fig. 6b), which were comparable to the literature\(^\text{19}\). The above results reveal that the response speed for MSCP was three orders of magnitude faster than MPFP. Figure 7 presents the stability and durability of the MSCP. Within the scanning time of about 2,000 s, no obvious degradation of photocurrent was observed for each curve measured before and after 40 days’ storage in a desiccator at room temperature, indicating excellent photocurrent stability of the MSCP device. Besides, it still kept a high photocurrent of 2.65 \(\mu\)A that only fell by 6\% after 40 days’ storage, meaningfully revealing a good durability of the natural MSCP device without any modification. However, it’s also worth mentioning that kept in test situations (atmosphere with a relative humidity of about 45 per cent), the MPFP device wore off within a few days while the MSCP still worked for a much longer time.

**Discussion**

Previous experimental studies of MAPbI\(_3\) optoelectronic devices, such as photodetectors and solar cells, are normally based on polycrystalline films. In the current study, we first revealed the much higher performance, based on single crystal, of the MAPbI\(_3\) photodetector. It is crucial to understand the nature of the high-performance of the as-fabricated MSCP. It undergoes various photophysical processes and dynamic interplays in bare MAPbI\(_3\) as the photoexcitation is triggered, such as absorption, generation of electron-hole pairs, charge transfer and recombination\(^\text{36}\). Firstly, the specific crystal structure and electronic structure of MAPbI\(_3\) provide appropriate chance for harvesting light while ensuring high efficiency. Bulk single crystal may play a better role in absorbing photons because it is much thicker than a thin-film. Once exposed to the illumination with a larger photoenergy than the band gap, MAPbI\(_3\) absorbs photons to generate a large number of electron-hole pairs \([h\nu \rightarrow e^- + h^+]\)^\text{19}. An applied voltage bias provides the local electric field for both MAPbI\(_3\) single crystal and its polycrystalline film counterpart, leading to separate the photogenerated electrons and holes and decrease the electron-hole recombination rates, which is of great importance for the high gain of the photodetector. After excitons dissociation, the electrons would migrate to the conduction band of MAPbI\(_3\) and further to the cathode, while the holes would flow to the valence band and further to the anode. During the carrier migration process, the resistance of the transporting tunnels made a difference between in MAPbI\(_3\) polycrystalline film and in MAPbI\(_3\) single crystal. For the former, numerous defects and extensive disorders impede the carrier migration and hinder the MAPbI\(_3\) photodetectors from achieving the optimal performance. As to the latter, the low trap density, which was dramatically reduced by 2 to 3 orders of magnitude\(^\text{23}\), reasonably give rise to the higher carrier mobility and much longer carrier diffusion length. As a result, significant performance improvements were eventually achieved for the MSCP.

In summary, centimeter-sized MAPbI\(_3\) bulk single crystals were successfully grown via the BSSG method. Optical characterization demonstrated excellent absorption in the visible region with an absorption cut-off edge towards 840 nm, which was broader than that of MAPbI\(_3\) polycrystalline film. A planar-type photodetector was fabricated on the (100) facet of MAPbI\(_3\) single crystal for the first time. The lowest detectable irradiance power density for MSCP was evaluated to be 2.12 nW cm\(^{-2}\), under which the highest R value of 953 A W\(^{-1}\) and and EQE of 2.22 \(\times\) 10\(^5\)\% were achieved. When exposed under 1 mW cm\(^{-2}\) illumination of 532 nm, the R values for MSCP and MPFP were estimated to be 2.55 A W\(^{-1}\) and 0.0197 A W\(^{-1}\), while the corresponding EQE values were calculated to be 5.95 \(\times\) 10\(^2\)\% and 4.59\%, respectively, demonstrating more than two orders of magnitude higher responsivity and EQE for MSCP. The transient photocurrent measurement showed MSCP had a very fast photoresponse rate. The rise time was 74 \(\mu\)s and the fall time was 58 \(\mu\)s, around three orders of magnitude faster than those measured in

![Figure 7. Photocurrent stability and durability of the as-fabricated MSCP.](image-url)
from diethyl ether, and dried at 333 K in a vacuum oven for 24 h. The prepared MAI, PbI₂ (99.5%,
urements, a polarization modulator, which composed of a fixed polarizer and a rotatable analyzer, was

power-dependent photoresponse characteristics of the device were measured by an optical chopper and a

**Characterization of MAPbI₃, Single Crystal.** Single crystal XRD data were collected on a Xcalibur,
Eos, Gemini device at 293(2) K using Mo Kα radiation (λ = 0.7107 Å). All calculations were performed
with programs from the SHELXTL crystallographic software package. Final least-squares refinement
with data having Fᵡ ≥ 2σ(Fᵡ) including anisotropic displacement parameters for all nonhydrogen
atoms. The structure was checked for missed symmetry elements on the model using PLATON. The
single crystal plates for optical characterization and device fabrication were obtained by cutting from the
oriented bulk single crystal followed by polishing to 1 mm in thickness. The as-prepared single crystal
plates were oriented by X-ray diffraction (XRD) spectroscopy (Bruker D8 Advance) operated with Cu Kα
radiation at 40 kV and 40 mA. X-ray crystal diffraction instrument (DX-2/4A) was also used to confirm
the orientation. The transmission spectrum was collected on a Lambda 950 UV-Vis-NIR spectrophotom-
eter (PerkinElmer).

**Device Fabrication.** Planar-type MSCP devices were fabricated by depositing 140 nm interdigital
gold-film electrodes via vacuum evaporation method on the (100) facet of MAPbI₃ single crystal
plate. The bridging-gap of electrodes width is about 20 μm, while the effective illuminated area of
MAPbI₃ single crystal was about 1.19 × 10⁻⁷ m². While the bare MAPbI₃ film was prepared according
to Seok’s method 20. CH₃NH₃I (MAI) was synthesized by mixing 27.86 ml CH₃NH₂ (40% in methanol,
Aladdin) and 30 ml HI (57 wt% in water, ACROS ORGANICS) through an ultrasound treatment. 1.33 ml methylamine (40%
water, Aladdin) was dissolved in 4 ml hydroiodic acid solution. The two solutions were
heated to 373 K respectively. They were kept at that temperature for 2 hours, and then they mixed.
Small angular black crystals about 3 mm in size were obtained by cooling down the solution from
373 K gradually to 330 K for 5 days. These small crystals were drawn out of the solution above 320 K
and served as seed crystals for the subsequent bulk single crystal growth. Harvesting at temperature
below 310 K would be harmful to the completeness of the seed crystals since it would incur the for-
mation of acicular (MA)₄PbI₆·2H₂O crystals 27,37. Bulk single crystals of MAPbI₃ were grown via the
bottom-seeded solution growth method. A carefully selected seed crystal was introduced into the
bottom of the growth solution by fixing it at the end of a Pt wire immersed in the growth solution at
373 K. The temperature was kept 373 K for 10 min to dissolve the outer surface of the seed crystal, then
it quickly dropped to 355 K and followed by a slow cooling rate until the desired size was obtained.
Subsequently, it dropped to 330 K at a slow cooling rate of 5 K per hour. Ultimately, the resultant
rhombic dodecahedral MAPbI₃ bulk single crystal was taken out from the growth solution at a tem-
perature higher than 320 K.

**Device Characterization.** The wavelength-dependent photoresponse measurements were performed
with a 300 W Xe lamp equipped with a manual monochromator. The photoresponse characteristics of
as-fabricated MSCP were investigated in the range from 275 nm to 790 nm with an interval of 25 nm. A
set of optical power meter was used to measure the incident powers. Besides, all the other irradiations
were achieved by using a 532 nm semiconductor laser with a spot diameter of about 3.00 mm. The electrical
characteristics except for the transient performances and irradiance power-dependent photoresponse
characteristics were collected by a Keithley 2400 SourceMeter. The high speed features and irradiance
power-dependent photoresponse characteristics of the device were measured by an optical chopper and a
precision Source/Measure Unit (Agilent B2911A). For irradiance power-dependent photoresponse meas-
urements, a polarization modulator, which composed of a fixed polarizer and a rotatable analyzer, was
used in order to obtain the variety of irradiance power densities. A gold thin film was utilized to achieve the weakest light below 10⁻³ mW cm⁻².

Acknowledgements
The authors would like to thank the financial support from the National Science Foundation of China (Nos. 51173097, 91333109 and 11174172) and the National Key Basic Research Program of China (No. 2013CB632900). The Tsinghua University Initiative Scientific Research Program and the Open Research Fund Program of the State Key Laboratory of Low-Dimensional Quantum Physics (No. KF201516) are acknowledged for partial financial support. Prof. Shengchun Qu and Dr. Kong Liu from the Institute of Semiconductors, Chinese Academy of Sciences, and Ms. Nan Li from department of chemistry, Tsinghua University are also acknowledged for valuable discussions.

Author Contributions
The contributions of each author to this study were as follows: Z.P.L. and Q.F.Y. conceived and designed the experiments. J.-L.S. contributed to the device measurements. Q.R.L. and L.J.Z. helped with the sample preparation of the single crystal of MAPbI$_3$. L.D.W helped with the sample preparation of the MAPbI$_3$ film. Y.W., L.L.L., S.L.P. and Q.L. contributed to crystal structure analysis. Z.P.L., Q.F.Y. and J.L.S. wrote the manuscript. All authors discussed the results and commented on the paper.
