The ability of a cell to move requires the asymmetrical organization of cellular activities. To investigate polarized cellular activity in moving endothelial cells, human endothelial cells were incubated in a Dunn chamber to allow migration toward vascular endothelial growth factor. Immunofluorescent staining with a specific antibody against caveolin-1 revealed that caveolin-1 was concentrated at the rear of moving cells. Similarly, monolayer scraping to induce random cell walk resulted in relocation of caveolin-1 to the cell rear. These results suggest that posterior polarization of caveolin-1 is a common feature both for chemotaxis and chemokinesis. Dual immunofluorescent labeling showed that, during cell spreading, caveolin-1 was compacted in the cell center and excluded from nascent focal contacts along the circular lamellipodium, as revealed by integrin β1 and FAK staining. When cells were migrating, integrin β1 and FAK appeared at polarized lamellipodia, whereas caveolin-1 was found at the posterior of moving cells. Notably, wherever caveolin-1 was polarized, there was a conspicuous absence of lamellipod protrusion. Transmission electron microscopy showed that caveolae, similar to their marker caveolin-1, were located at the cell center during cell spreading or at the cell rear during cell migration. In contrast to its unphosphorylated form, tyrosine-phosphorylated caveolin-1, upon fibronectin stimulation, was associated with the focal complex molecule phosphopaxillin along the lamellipodia of moving cells. Thus, unphosphorylated and phosphorylated caveolin-1 were located at opposite poles during cell migration. Importantly, loss of caveolin-1 polarity by targeted down-regulation of the protein prevented cell polarization and directional movement. Our present results suggest a potential role of caveolin polarity in lamellipod extension and cell migration.

Endothelial cell migration is a key step toward angiogenesis, a process that is required in a variety of physiological and pathological conditions, such as embryonic development, wound healing, tissue regeneration, and tumor growth and metastasis. A clear understanding of how endothelial cells sense chemoattractants, organize signaling asymmetry, and make a directional movement is of pivotal importance in the biology of normal cells, as well as tumor angiogenesis. Like other types of crawling cells, migrating endothelial cells acquire a series of spatially polarized features. The front of a migrating cell generates protrusive force associated with lamellipod or filopod protrusion coupled with the development of new cell adhesions to the extracellular substrates. Cell contractility is required to allow the retraction of the body and rear of the cell. Apart from the surface features, such as lamellipodia and microspikes, relatively little is known about the “directional sensing” machinery that orients locomotion machinery in endothelial cells.

Caveolae (also termed plasmalemmal vesicles) are specialized microdomains on the plasma membrane with a size of 50–100 nm (1). In addition to transcytosis and endocytosis, a good body of evidence has shown that caveolae compartmentalize and integrate signaling events at the cell surface (2–4). A variety of protein and lipid signaling molecules involved in VEGF receptor and integrin-mediated signaling are concentrated in caveolae. These include VEGF-R2 (KDR), non-receptor tyrosine kinases (such as Src, Yes, and Fyn), PI 3-kinase, Rac1, Cdc42, and RhoA, and phosphatidylinositol (4–9). These observations suggest a potential role of caveolae in mediating signal transduction involved in cell migration.

The major structural proteins of caveolae are the caveolins. Four caveolins encoded by three different genes have been identified. Endothelial cells abundantly express caveolin-1 and -2 (but not caveolin-3, which is muscle-specific) (10). Caveolin-1 interacts with a number of signaling proteins, including Src family kinases, Go subunits, H-Ras, protein kinase C, endothelial nitric-oxide synthase, PI 3-kinase, integrins, and epidermal growth factor receptor (11–14). In general, interaction between caveolin via the caveolin scaffolding domain and signaling proteins leads to inactivation of the target proteins (11). Thus, caveolin may function as an endogenous negative regulator of many signaling molecules. Given this view, one would predict that down-regulation of caveolins may lead to an increase in basal activity of signaling pathways and subsequent cellular activity, such as cell motility. In accordance with this, an attractive hypothesis would be that mere translocation of caveolin (i.e. caveolin polarization), without a substantial change in the expression level, would reinforce an inhibitory effect on one part of the cell (i.e. the cell rear) but release its inhibitory activity on the other side (i.e. the leading edge). This hypothesis is supported by recent studies showing caveolae and caveolin-1

asymmetry during cell migration (15–18). However, whether caveolin-1 polarity affects endothelial cell lamellipod protrusion and migration is not known.

In the present study, we demonstrated that caveolin-1 and caveolae were excluded from the leading edge and directed toward the rear of migrating cells. Interestingly, a subpopulation of caveolin-1 that was phosphorylated on tyrosine 14 specifically moved to focal adhesions at the leading edge of migrating cells. Importantly, loss of caveolin-1 polarity by targeted knockdown of the protein prevented endothelial cell polarization and impeded cell directional movement.

EXPERIMENTAL PROCEDURES

Materials—Reagents and other supplies were obtained from the following commercial sources: antibodies against caveolin-1, phospho-caveolin-1, and FARK from BD Biosciences (San Diego, CA). Phalloidin–TRITC and fibronectin were purchased from Sigma. Antibodies against integrin β1, green fluorescent protein, and c-Myc were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Goat serum, fluorescein isothiocyanate, and Rhodamine Red-X-conjugated secondary antibodies were obtained from Jackson Immuno-Research Laboratories (West Grove, PA). Antibodies against paxillin, phosphopaxillin (pTyr-31), and caveolin-1 (GenBank™ accession number BC009685) were obtained from Cell Signaling Technology (Danvers, MA). Antibodies against α-actin, vimentin, cofilin, integrin α5, and caveolin-1 or other signaling molecules. Bound primary antibodies were detected using fluorescein- or rhodamine-conjugated secondary antibodies. The immunostained cells were mounted in the presence of Slow-Fade reagent. Immunostaining was visualized and photographed using a Zeiss LSM 510 confocal microscope.

Transmission Electron Microscopy—Endothelial cells were either sparsely seeded onto gelatin-coated plates for 1 h or seeded near confluent, scratched multiply with a 200-μl pipette tip, and incubated to allow cell migration. The cells were then fixed with 2.5% glutaraldehyde in 0.1 M phosphate buffer and scraped into a microcentrifuge tube. The cells were pelleted and post-fixed with osmium tetroxide. After fixation, the cells were infiltrated with a propylene oxide/epon mixture and stained with uranyl acetate and lead citrate. Thin sections of samples were examined under a JEOL 1220 transmission electron microscope. On randomly taken photographs, the number of caveolae at the leading edge and the cell center of spreading cells or at the leading edge and the cell posterior of migrating cells was determined.

RESULTS

Caveolin-1 Is Located at the Rear of Migrating Cells—Previous studies have shown that caveolin-1 displays polarization in migrating cells. For instance, caveolin-1 accumulated at the trailing edge of scratch-induced migrating bovine aortic endothelial cells or shear stress-stimulated bovine aortic endothelial cells (15, 16). On the other hand, caveolin-1 was concentrated at the leading edge of fibroblast growth factor–stimulated migrating bovine aortic endothelial cells (16). To assess whether the discrepancy of caveolin-1 polarization resulted from chemotactic gradient, we employed two kinds of cell migration systems: chemokinesis to measure random walk using monolayer denudation (also termed scratch motility assay) and chemotaxis to measure directional movement using the Dunn chamber. Six hours after scaring, the endothelial cells began to migrate into the wound gap. The closure of wound gaps took ~24 h. Immunofluorescent staining with a specific antibody against caveolin-1 showed that the majority of caveolin-1 moved to the rear of the migrating cell as a mechanism to sequester it away from signaling proteins that direct cell motility at the leading edge. Here, we focused on nascent focal adhesions at the leading edge revealed by immunostaining with specific antibody against integrin β1 and FAK. Human
umbilical vein endothelial cells were seeded on fibronectin-coated coverslips. Within 1 h after seeding, most cells spread radially. As shown in Fig. 2, caveolin-1 was localized compactly in the center of the spreading cells (Fig. 2, a and g) and was excluded from nascent focal contacts along the circular lamellipodium revealed by FAK or integrin β₁ staining (Fig. 2, b and h). After incubation for several hours, focal contacts appeared in the polarized lamellipodium at the leading edge of migrating cells (Fig. 2, e and k). Caveolin-1 signal was now relocated at the rear of most moving cells (Fig. 2, d and j). These data confirm that caveolin-1 moves to the opposite pole of a migrating cell, compared with FAK and β₁ integrin at the leading edge.

Exclusion of Caveolae from Lamellipodia—Like many other terminally differentiated cells, such as adipocytes, fibroblasts, and skeletal muscle cells, endothelial cells possess a large number of caveolae (1, 22). Rapid freeze, deep etch images show that caveolae have a striated coat and contain the integral 22-kDa membrane protein, caveolin (23). The coat protein is a reliable marker for tracing caveolae trafficking in live cells (24).

Based on our results described above demonstrating that caveolin-1 was centrally concentrated in spreading cells, we predicted that caveolae may be centrally localized as well. To assess the location of caveolae, endothelial cells were seeded for 1 h to allow spreading and then fixed and processed for electron microscopy analysis. As shown in Fig. 3, caveolae were localized abundantly at the cell center of spreading cells (Fig. 3A, b, arrowheads; Fig. 3B). Few, if any, caveolae were found at the lamellipod protrusion (Fig. 3B). When cells were migrating, caveolae, like their marker caveolin-1, were now concentrated at the cell rear (Fig. 3A, d, arrowheads; Fig. 3C), opposite the lamellipodium. In contrast, few, if any, caveolae were found at the leading edge of migrating cells (Fig. 3A, c; Fig. 3C). Again, these results indicate that caveolae, along with caveolin-1, were excluded from the leading edge of migrating cells.

Phosphocaveolin-1 Is Co-localized with Focal Complex Molecules at the Leading Edge of Migrating Cells—Caveolin is one of the major v-Src substrates in Rous sarcoma virus-transformed chicken embryo fibroblasts (25). Stimulation of A431 cells with EGF or NIH 3T3 cells with hyperosmotic stress leads to phosphorylation of caveolin-1 on tyrosine 14, and the phosphorylation events are associated with focal adhesions (26, 27). To assess whether phosphorylation of caveolin-1 occurred and where the phosphorylation took place during cell migration, endothelial cells were treated with fibronectin and dually stained with specific antibodies against caveolin-1 (fluorescein isothiocyanate, d) and integrin β₁ (Rhodamine Red-X, e). Note that caveolin-1 signal was again localized at the rear and trailing edge of moving cells (green arrowheads in d and e) opposite the leading edge (green arrows in e).
levels by >80%. Notably, knockdown of caveolin-1 dramatically impeded the ability of endothelial cells to polarize, which instead maintained a near-circular lamellipodium (Fig. 5A, b), whereas control siRNA- or mock-treated cells were able to polarize as normal (Fig. 5A, a and c). A comparison of Cav-1 siRNA-treated with control siRNA- or mock-treated cells revealed a significant reversal of the ratio of circular to polarized cells in the Cav-1 siRNA group, with caveolin-1 knockdown inhibiting the polarization of endothelial cells (Fig. 5B).

Knockdown of Caveolin-1 Inhibits Endothelial Cell Directional Movement—Given the nature of caveolin-1 as a scaffolding protein to organize and sequester signaling molecules, caveolin-1 may coordinate cellular activities between the leading edge and rear of a moving cell. In response to environmental stimulation, cells exclude caveolin-1 from the leading edge by an unknown mechanism and eliminate its inhibitory action on signaling molecules that are involved in lamellipod protrusion. At the same time, caveolin-1 concentrates and reinforces its inhibitory action at the posterior of a polarized cell. Hence, a cell may sense and move directionally by exclusion of caveolin-1 from the leading edge. In accordance with this, loss of caveolin polarity would inhibit directional cell movement. To test this hypothesis, HUVECs were transfected with caveolin-1 siRNA and subjected to chemotactic response to serum using a well characterized microchemotaxis chamber system (28). As shown in Fig. 6, loss of caveolin-1 polarity by knockdown of the protein dramatically reduced the number of migrating endothelial cells by >3-fold over mock or control siRNA-treated cells. Thus, our results indicate that loss of caveolin-1 asymmetry impeded endothelial cell directional movement.

DISCUSSION

We have demonstrated that caveolin and caveolae polarized regardless of VEGF-induced directional movement or monolayer scraping-induced random walk. Polarization was found at the rear of moving cells in both models. Notably, during cell spreading or migration, extension of the leading edge and protrusion of lamellipodia were not observed in the area with higher caveolin-1 signal. Although caveolin has an intimate relationship with the cytoskeleton, little is known about the function of the protein in cell migration. In the present study, we have shown that loss of caveolin polarity by knockdown of the protein dramatically inhibited cell polarization and impeded cell directional movement. Our results indicate an essential role of caveolin polarity in lamellipod protrusion and in orienting directional movement in endothelial cells. Fig. 7 depicts a model of cell polarization in which caveolin-1 is located at the rear of a moving cell, where it prevents lamellipod protrusion. Upon phosphorylation at tyrosine 14, caveolin-1 is released from caveolae and associated with focal adhesion sites at the leading edge, where it may mediate the recruitment of Csk and affect the formation of focal adhesions (29).

Our present results are consistent with previous reports demonstrating caveolin and caveolae polarization in bovine aortic endothelial cells in response to shear stress (15), monolayer scraping, or fibroblast growth factor stimulation (16). Our result of growth factor-induced caveolin relocation at the cell posterior stands in contrast to a recent report that caveolin is located to the leading edge of fibroblast growth factor-stimulated transmigrating bovine aortic endothelial cells (16). Interestingly, the leading edge accumulation of caveolin-1 requires
phosphorylation of the protein at tyrosine 14, which is consistent with our finding that tyrosine-phosphorylated endogenous caveolin-1 associated with focal adhesion molecules at the leading edge (see Fig. 4). This study did not determine whether the polarized endogenous caveolin-1 is tyrosine-phosphorylated; therefore, it is not clear whether they were observing forward relocation of non-phosphorylated or phosphorylated caveolin-1. Manes et al. (30) showed recently the relocation of lipid rafts to the leading edge of insulin-like growth factor-I-stimulated MCF-7 denocarcinoma cells. Because the study did not examine the location of caveolin-1, a marker of caveolae, it is unclear that the relocation of lipid rafts represents caveolae or non-caveolae rafts. Thus, caveolin and caveolae relocation depends on the modes of cell migration and is cell-type-specific. Nevertheless, the observation that different stimulations lead to caveolin and caveolae relocation suggests that it is a general mechanism for cells to spatially organize subcellular activities that direct cell motility.

The majority of caveolin-1 is found at the cell surface and associated with caveolae (23, 31). Some Golgi-associated caveolin-1 is in transit from its site of synthesis in the endoplasmic reticulum to the cell surface (32). The recycling of surface caveolin-1 through the Golgi apparatus involves the directional movement of the molecule from caveolae to the lumen of the endoplasmic reticulum and onto the Golgi apparatus (33, 34). One possible mechanism that directs caveolae and caveolin-1 polarization is that recycling caveolar vesicles accumulate at the cell rear during migration. Another possibility is that caveolin and caveolae accumulate at the cell posterior as a result of differential movement of other organelles. The experimental observation that cell polarization signals are upstream and independent of those triggering cell motility suggests that phosphorylation of the protein at tyrosine 14, which is consistent with our finding that tyrosine-phosphorylated endogenous caveolin-1 associated with focal adhesion molecules at the leading edge (see Fig. 4). This study did not determine whether the polarized endogenous caveolin-1 is tyrosine-phosphorylated; therefore, it is not clear whether they were observing forward relocation of non-phosphorylated or phosphorylated caveolin-1. Manes et al. (30) showed recently the relocation of lipid rafts to the leading edge of insulin-like growth factor-I-stimulated MCF-7 denocarcinoma cells. Because the study did not examine the location of caveolin-1, a marker of caveolae, it is unclear that the relocation of lipid rafts represents caveolae or non-caveolae rafts. Thus, caveolin and caveolae relocation depends on the modes of cell migration and is cell-type-specific. Nevertheless, the observation that different stimulations lead to caveolin and caveolae relocation suggests that it is a general mechanism for cells to spatially organize subcellular activities that direct cell motility.

The experimental observation that cell polarization signals are upstream and independent of those triggering cell motility suggests that...
asymmetric caveolin redistribution is not the consequence of cell movement (35, 36).

Caveolin-1 was first identified as a major tyrosine-phosphorylated protein in v-Src-transformed chicken embryo fibroblasts (25). Microsequencing of Src-phosphorylated caveolin-1 revealed that phosphorylation occurs within the extreme N-terminal region of the full-length of caveolin-1 (37). Site-directed mutagenesis showed that tyrosine 14 is the principal substrate for Src kinase (37). Recent studies have shown that caveolin-1 undergoes phosphorylation at tyrosine 14 in response to a number of stimulations, such as insulin, EGF, and osmotic stress. Tyrosine-phosphorylated caveolin-1 provides a docking site recruiting SH2 domain-containing proteins, such as Grb7 and Csk, and augments EGF-stimulated cell migration (26, 29). Because Grb7 contains an SH2 domain and a phosphotyrosine-interacting region (38), it may function as a bridge linking phosphorylated caveolin-1 to other tyrosine-phosphorylated proteins, such as FAK (39). In the present study, we observed a rapid phosphorylation of caveolin-1 at tyrosine 14 upon fibronectin stimulation. Importantly, unlike the unphosphorylated caveolin-1, tyrosine-phosphorylated caveolin-1 was co-localized with focal complex molecules at the leading edge of migrating cells. The discovery that tyrosine-phosphorylated caveolin-1 and unphosphorylated caveolin-1 polarize at two opposing poles of moving cells is intriguing, although the mech-

**Fig. 5.** Knockdown of caveolin-1 prevents endothelial cell polarization. HUVECs were transfected with either caveolin-1 siRNA or control siRNA, as described under “Experimental Procedures.” A. forty-eight hours after transfection, HUVECs were seeded on fibronectin, incubated to allow migration, fixed, and then subjected to dual immunofluorescent staining with specific antibody for caveolin-1 (fluorescein isothiocyanate) or paxillin (Rhodamine Red-X). Note that mock- and control siRNA-treated cells were able to polarize (a and c). In contrast, knockdown of caveolin-1 impeded polarization of the cells (b), which instead displayed a near-circular lamellipodium. B, the effect of caveolin-1 knockdown on cell polarization was quantified by counting circular versus polarized cells from eight randomly selected views corresponding to each of the treatments. Data are the means ± S.D. C, caveolin-1 protein levels were specifically knocked down by the caveolin-1-specific siRNA.

**Fig. 6.** Knockdown of caveolin-1 inhibits endothelial cell directional movement. HUVECs were transfected with either caveolin-1-specific or control siRNA or alternately were mock transfected. Forty-eight h after transfection, the cells were placed over a polycarbonate filter and allowed to migrate through 8-µm pores to an adjacent compartment in response to serum stimulation. After a 3-h incubation, the cells that migrated to the serum compartment were counted. Note that knockdown of caveolin-1 dramatically inhibited cell migration compared with control siRNA- or mock-treated cells. Data are means ± S.D.

rected mutagenesis showed that tyrosine 14 is the principal substrate for Src kinase (37). Recent studies have shown that caveolin-1 undergoes phosphorylation at tyrosine 14 in response to a number of stimulations, such as insulin, EGF, and osmotic stress. **Fig. 7.** Proposed model demonstrating caveolin-1 polarity and control of lamellipod protrusion. Caveolin-1, the integral membrane protein of caveolae, is believed to interact with signaling molecules. Immunofluorescent staining of a resting cell (left) with antibody for caveolin-1 reveals a punctate staining pattern at the cell surface (small dots, left). Upon chemotactic stimulation (right), caveolin-1 is excluded from the leading edge and relocates to the cell posterior (small dots, right) where it prevents lamellipod protrusion (T bar, right). In contrast, tyrosine-phosphorylated caveolin-1 is separated from caveolae and associated with focal complexes (Int/FAK) at the leading edge (small crosses, right). Thus, caveolin-1 polarity may serve to spatially organize cellular activity that mediates lamellipod protrusion. Loss of caveolin-1 polarity by targeted knockdown of the protein impedes cell polarization.
anism underlying this is unclear. Therefore, during cell migration, phosphorylated caveolin-1 located at focal complexes along the leading edge might couple integrin to non-receptor tyrosine kinases, such as Src, Fyn, and FAK, whereas unphosphorylated inhibitory caveolin-1 is relocated to the cell rear.

Our present results demonstrated that loss of caveolin polarity impede endothelial cell polarity and directional movement and suggest that caveolin may play an important role in angiogenesis. This idea is supported by a variety of studies showing that caveolin affects capillary formation. We and others have shown recently that antisense-mediated down-regulation of caveolin-1 inhibits capillary tubule formation (40, 41). Up-regulation of caveolin-1 in microvascular endothelial cells enhances capillary tubule formation via the caveolin-1 scaffolding domain (41). The importance of caveolin-1 in angiogenesis is further emphasized by a recent study demonstrating a reduced infiltration of blood vessels into fibroblast growth factor-supplemented Matrigel plugs in caveolin-1 knock-out mice (42). In the same mice, tumor weight, volume, and blood vessel density are reduced due to lack of caveolin-1 and caveolea (42).
