**ABSTRACT.** In July 2017, twenty cattle of a free-grazing herd were found to be infested with leeches in the mouth. Main signs were bloody sialorrhea and/or a purple-red colour of the lower lip. Leeches, in a variable number (1 to 3) per animal, were found at the lingual frenulum or on the sublingual vestibular mucosa and were morphologically identified as *Limnatis nilotica*. To the best of our knowledge, this is the first report of cattle infestation by *L. nilotica* in Italy. Besides recalling the attention to leech infestation and suggesting its inclusion in the differential diagnosis of animals with suggestive signs, this short report also provides practitioners with easy-going morphological keys for proper diagnosis and discrimination among species.

**KEY WORDS:** cattle, leech infestation, *Limnatis nilotica*, oral cavity, Sicily

Leeches belong to the Annelida phylum and Hirudinea class [14], and are world-wide distributed. Leeches are segmented hermaphroditic blood feeding ectoparasites of man, domestic and wild animals, as well as invertebrate creatures [3]. Leeches are featured by two prominent suckers (i.e., anterior and posterior) that allow them to grip the surface of the prey while they suck the host’s blood. The leech’s mouth located within the anterior sucker, is equipped with a set of razor-sharp jaws that are used to open wound in the prey, while the muscular pharynx pumps the blood into the leech’s digestive tract. A salivary gland secretes the hirudin, an anticoagulant substance that prevents coagulation of the blood [11, 12].

Leeches have a dual significance, indeed, beside the primary role as blood-feeder parasites, some species may also act as vectors of other pathogens. Noteworthily, leeches are acknowledged vectors of protozoans, including *Trypanosoma* spp. [30] causing disease in humans and/or livestock [18, 19]. The host range of leeches is fairly broad and is not restricted to a single vertebrate class. Therefore, these invertebrates would ingest a range of unrelated trypanosomes with their blood meals, and, in turn, may expose a wide range of vertebrates to the trypanosomes they carry [18, 19].

Several species of leeches have been proven to be beneficial to humans, being *Hirudo medicinalis*, known as the European medicinal leech, the best-known species used for bloodletting in humans [20], though there are other medicinal leech species such as *Hirudo troctina* and *Haementeria officinalis* [15]. Other leech species can lead to damages of different severity in the hosts. In this regard, one of the most important species is *Limnatis nilotica*, commonly known as horse leech or Nile leech, this species occurs in lakes and streams in southern Europe, Middle-East countries and North Africa [2, 5, 25, 26].

*Limnatis nilotica* may enter the animal body through drinking from contaminated water and usually attaches to the oral cavity or respiratory passages [14, 17, 37]. Indeed, this species is not able to pierce the skin of mammals but it sucks blood from the mouth or nasal mucosa causing inflammation and other damages [24]. Though several animal species (e.g. cow, sheep, goat, horse, dog and pig) and human can be infested [8, 13], hirudiniasis by *L. nilotica* is considered negligible and only few reports are available in literature (see Table 1). The rareness of *L. nilotica* reports in European countries may be related to the reclamation of wetlands as well as to the good quality of breeding standards which mostly use clean drinking water. However, one might speculate that the paucity of reports claiming the finding of *L. nilotica* could be due because unnoticed or misidentified.

Here we report the first signalling of oral hirudiniasis by *L. nilotica* in cattle in Italy; additionally, we also provide easy identification keys that would allow proper and easy diagnosis in case of leech infestation.

In July 2017, cattle, of a cattle-goat mixed herd located in the province of Messina (southern Italy, 38.0239N; 14.7298E; 400 m a.s.l.) were referred for veterinary consultation.

Upon physical examination cattle showed bloody sialorrhea and/or reddish colouring of the lower lip (Fig. 1A), weight loss and restlessness when the oral cavity was touched from the outside. At the opening of the oral cavity, a variable number of live leeches, one to three per cattle, were found attached at the lingual frenulum and/or on the sublingual vestibular mucosa (Fig. 1B–C). The leeches were detached and removed by a gentle traction with forceps, stored in plastic vials containing 70% alcohol and, thereafter, sent to the Unit of Parasitology at the Department of Veterinary Sciences (University of Messina, Messina, Italy) for identification. Once in laboratory, the leeches were observed under a stereomicroscope and photographed with the aid of a digital camera (AxioCam MRc, Carl Zeiss, Göttingen, Germany) mounted directly on the microscope. Additionally, some specimens were also routinely processed for scanning electron microscopy (SEM) as described elsewhere [38] and observed with an SEM Zeiss EVO 10 MA (Carl Zeiss Microscopy GmbH, Jena, Germany).

Twenty out of 60 cattle were found leech infested; the infestation was not associated with age of animals as either young (5–6 months of age) and adults (5–6 years) were found parasitized.

The leeches wherein investigated measured 2.5–3.0 cm in length and 0.8–1.0 cm in width with dark green-black colour on the dorsal side and a lighter colour on the ventral side.

The well-developed posterior sucker (Fig. 2B) had a diameter equal to the maximum width of the body (1 cm), while the anterior sucker with three lobes was featured by a median ventral furrow (Fig. 2C). The anterior sucker showed 10 eye spots arranged in lateral crescents. Triple jaws, consisting of one dorso-medial and asymmetrical pair of ventro-lateral jaws were observed inside the oral cavity and surrounded the oral opening (Fig. 3B). The jaws appeared rounded, soft and light grey with clearer spots. A number of papillae were observed on both sides of jaws (Fig. 3C) and a row of tooth craters, irregular in size, shape and spacing, was observed on their edge (Fig. 3C). Specifically, some specimens herein analysed showed 48 tooth craters for each jaw whereas other ones showed 57 tooth craters each.

The morphological structures of the anterior extremity observed at the stereomicroscope were also described with SEM (Fig. 4).

All the collected leech specimens were identified as *L. nilotica* according to morphological keys reported by Minelli [24], Nakano et al. [28], Negm-Eldin et al. [29] and Orevi et al. [31].

Macro- and microscopic differences among the species *H. medicinalis*, *L. nilotica* and *Haemopis sanguisuga* are shown in Figs. 2A and 3A, in order to give a basic recognition guide to medicinal and non-medicinal leech species commonly found in Italian territory.

The genus *Limnatis* includes three species, namely *L. nilotica*, *L. bacescui*, and *L. paluda* [36]. The leech taxonomy, at the species level and higher, is in a revolutionary phase so far. Little care has been devoted till now to represent the genera in molecular studies by their type species, and the species by their topo-type populations, though this approach remains the most reliable tool for assuring the taxonomical identity of specimens. Molecular evidences are available for *L. nilotica* and for *L. paluda* [28], whereas no molecular studies are available for *L. bacescui*. Despite the species in the genus *Limnatis* are well-known as nasal leeches, the taxonomic status of each is far from being clarified. Also, each nominal species of the genus *Limnatis* should be reviewed based on specimens collected from the type locality. The type locality of *L. nilotica* is Egypt, while *L. paluda* has been reported to occur mainly in the Middle-East [4, 10, 20]. The species *L. bacescui* was signalled only from its type locality, Romania (Dobruja) [22].

To the best of our knowledge, the present article, for the first-time, reports cattle infestation by the leech *L. nilotica* in Italy. The morphological structures of the anterior extremity of the examined specimens, particularly the jaws and the number of tooth craters for each jaw allowed the identification to species level. Effectively, it has been stated that *L. paluda* possesses fewer tooth

---

**Table 1. Reports of *Limnatis nilotica* infestation in several animal species**

| Animal species | Country | Reference |
|----------------|---------|-----------|
| Human          | Turkey  | Ağin et al. 2008 [1] |
| Cattle         | Iran    | Bahmani et al. 2012 [3] |
|                | Libya   | Negm-Eldin et al. 2013 [23] |
| Dog            | Iran    | Rajaei et al. 2014 [28] |
|                | Italy   | Raele et al. 2015 [27] |
| Goat           | Libya   | Negm-Eldin et al. 2013 [23] |
|                | Iran    | Bahmani et al. 2013 [6] |
| Sheep          | Libya   | Negm-Eldin et al. 2013 [23] |
|                | Iran    | Bahmani et al. 2013 [6] |
| Donkey         | Iran    | Bahmani et al. 2014 [4] |
| Camel          | Iraq    | Al-Ani and Al-Shareefi 1995 [2] |

**Fig. 1.** A cow with bloody sialorrhea due to *Limnatis nilotica* infestation (A); *L. nilotica* (arrow) attached to oral cavity of a cattle (B); specimen of *L. nilotica* detached from a cattle (C).
craters on each jaw (no. 30–47) compared to *L. nilotica* whose jaws own no. 45–60 tooth craters [21, 27]. In addition, *L. bacescui* possessed 50–54 teeth on each jaw [22]. Several surveys carried out in the Middle-East countries reported *L. nilotica* in a large number of animal species such as cattle, donkey, sheep, goat [5, 6], camel [2], dog [34] and humans [1]. Together all these findings suggest that *L. nilotica* is a generalist blood feeder rather than a host-specific parasite.

In Italy, this leech species has been reported in aquatic environment of Tuscany, Campania, Apulia, Basilicata, Sicily and Sardinia [24]. A case of *L. nilotica* infestation was described in human from Naples [24] and, more recently, in a dog from Apulia.
