**Abstract**

*Brassica napus* (canola) cultivars and isolates of the blackleg fungus, *Leptosphaeria maculans* interact in a ‘gene for gene’ manner whereby plant resistance (*R*) genes are complementary to pathogen avirulence (*Avr*) genes. Avirulence genes encode proteins that belong to a class of pathogen molecules known as effectors, which includes small secreted proteins that play a role in disease. In Australia in 2003 canola cultivars with the *Rlm1* resistance gene suffered a breakdown of disease resistance, resulting in severe yield losses. This was associated with a large increase in the frequency of virulence alleles of the complementary avirulence gene, *AvrLm1*, in fungal populations. Surprisingly, the frequency of virulence alleles of *AvrLm6* (complementary to *Rlm6*) also increased dramatically, even though the cultivars did not contain *Rlm6*. In the *L. maculans* genome, *AvrLm1* and *AvrLm6* are linked along with five other genes in a region interspersed with transposable elements that have been degenerated by Repeat-Induced Point (RIP) mutations. Analyses of 295 Australian isolates showed deletions, RIP mutations and/or non-RIP derived amino acid substitutions in the predicted proteins encoded by these seven genes. The degree of RIP mutations within single copy sequences in this region was proportional to their proximity to the degenerated transposable elements. The RIP alleles were monophyletic and were present only in isolates collected after resistance conferred by *Rlm1* broke down, whereas deletion alleles belonged to several polyphyletic lineages and were present before and after the resistance breakdown. Thus, genomic environment and exposure to resistance genes in *B. napus* has affected the evolution of these linked avirulence genes in *L. maculans*.

**Introduction**

The fungus *Leptosphaeria maculans* causes blackleg (phoma stem canker) and is the major disease of *Brassica napus* (canola) worldwide [1]. The major source of inoculum is wind-borne ascospores, which are released from insecticidal fruiting bodies on infected stubble (crop residue) of previous crops and can be transmitted several kilometres. This fungus has a ‘gene for gene’ manner whereby plant resistance (*R*) genes are complementary to pathogen avirulence (*Avr*) genes. Avirulence genes encode proteins that belong to a class of pathogen molecules known as effectors, which includes small secreted proteins (SSPs), which are cysteine-rich, share no sequence similarity with genes from other species, are often highly polymorphic between isolates of a single species and are expressed highly in planta [12]. The *AvrLm1*, *AvrLm4*-7 and *AvrLm6* proteins of *L. maculans* are effector molecules with an avirulence function. *AvrLm6* and *AvrLm4*-7 encode SSPs with six and eight cysteine residues, respectively, whilst the *AvrLm1* protein, which is also a SSP, has only one cysteine [8,9,10].

*Leptosphaeria maculans* undergoes sexual recombination prolifically and populations can rapidly adapt to selection pressures imposed by the host such as exposure to resistance conferred by single or major genes. This situation increases the frequency of virulent isolates and can cause resistance to break down, often resulting in severe yield losses [13]. Three examples of
A summary of the paper:

The fungus Leptosphaeria maculans causes blackleg, the major disease of canola worldwide. Populations of this fungus rapidly adapt to selection pressures such as the extensive sowing of canola with particular disease resistance genes. This can lead to a breakdown of resistance and severe economic losses. We describe mutations in key fungal genes involved in the interaction with canola, and we report the first large scale study of evolutionary processes affecting such genes in any fungal plant pathogen. We relate these changes to the genomic environment of these genes and to the breakdown of disease resistance in canola.

In this paper we relate changes in the types and frequencies of mutations in genes including AvrLm1 and AvrLm6 to the selection pressure imposed by extensive regional sowing of B. napus cultivars with sylvestris resistance.

Results

Virulence of Australian isolates of L. maculans and analysis of mutations at AvrLm1 and AvrLm6

In preliminary experiments to see if the breakdown of 'sylvestris resistance' in B. napus seen in the field [15] correlated with changes in frequency of virulence towards Rlm1 in individual L. maculans isolates, 11 isolates collected prior to the breakdown (before 2004) and 12 isolates collected after the breakdown (2004 onwards) were screened for virulence on B. napus cultivars Q2 (with Rlm3) and Columbus (Rlm1, Rlm3). Cotyledons of 14 day old plants were inoculated with individual isolates and symptoms were scored 17 days later. All isolates were virulent on the susceptible control, cv. Q2. Ten of the 11 isolates collected prior to 2004 were avirulent on the Rlm1-containing cultivar, Columbus. However, seven of ten isolates collected from 2004 onwards were virulent towards Rlm1 (Table 1). A subset of these isolates was inoculated onto the B. napus cultivar Aurea (Rlm6). Of seven of the 11 isolates collected prior to 2004, only one was virulent towards Rlm6. However, of 12 isolates collected from 2004 onwards, eight were virulent towards Rlm6 (Table 1). These results suggested that there was a significant change in frequencies of virulent alleles of AvrLm1 and AvrLm6 associated with breakdown of 'sylvestris resistance'. These isolates were then genotyped at the AvrLm1, AvrLm6 and mating type loci using PCR-based screening [20,22,24] and as expected, the virulence phenotypes corresponded with avrLm1 and/or avrLm6 genotypes (Table 1).

Changes in allele frequencies were then examined in a total of 295 Australian isolates. Of these 137 were collected between 1987 and 2003, prior to the breakdown of sylvestris resistance, whilst the remaining 158 isolates were collected between 2004 and 2008, after the resistance breakdown (Table S1). These isolates were collected from stubble of a range of canola cultivars with different resistance genes. One third of the isolates had a deletion of AvrLm1 (Table 2), whilst 63% had the allele of isolate v23.1.3, whose genome has been sequenced. Alleles of this isolate hereafter are referred to as wild type alleles (e.g. AvrLm1-0). As expected, isolates with AvrLm1-0 were avirulent towards Rlm1 (Tables 1 and 2). The remaining eight isolates comprised four alleles with coding sequence changes conferring non-synonymous substitutions (I225K and/or H155Y). Isolates harbouring these alleles were avirulent on the Rlm1-containing B. napus line (Table 1). Thirteen alleles of AvrLm6 were detected (Table 2). AvrLm6 was deleted in 20% of isolates, thus conferring virulence towards Rlm6, whilst 24% had the allele of the sequenced isolate and conferred avirulence towards Rlm6 (Tables 1 and 2). Other isolates virulent towards the Rlm6-containing cultivar had alleles with stop codons conferred by base changes remiscent of RIP mutation. Accordingly, allele sequences were analysed by RIPCAL, a software tool that visualises the physical distribution of RIP mutation and reports a RIP dominance score indicating the degree of RIP in each sequence. Sequences with RIP dominance scores >1 are highly RIP-affected having a high proportion of CpA to TpA or TpG to TpC RIP mutations [25]. RIPCAL analysis did not detect RIP in any AvrLm1 alleles, but detected RIP in seven AvrLm6 alleles. These RIP mutations resulted in numerous non-synonymous changes as well as premature stop codons (between 4 and 6), which were within all RIP-affected alleles (Table 2). Southern hybridisation results suggest that there is only a single
copy of the AvrLm6 locus within isolates harbouring the RIP alleles (Figure S1). The remaining alleles of AvrLm6 (AvrLm6-1, -2, -3 and -4) harboured single or few nucleotide changes leading to synonymous or amino acid substitutions (G123C, K127E, F54L) compared to isolate v23.1.3 (AvrLm6-0). These amino acid substitutions were generated via non-RIP like mutations (henceforth referred to as non-RIP amino acid substitutions). Isolates harbouring AvrLm6-1, AvrLm6-3 or AvrLm6-4 alleles were avirulent towards cv. Aurea, whilst the four isolates harbouring the AvrLm6-2 allele (G123C) were virulent (Table 1).

No RIP-affected alleles were present in isolates collected prior to the breakdown of sylvestris resistance. However, the 158 isolates collected after the breakdown had seven AvrLm6 RIP alleles (frequency of 8.9%) and there was a very large increase in the frequency of deletion alleles of AvrLm6 (22.6 to 41.8%) and AvrLm6 (4.4 to 38.7). This was a nine-fold increase in frequency of avrLm6 (Table S2). Thirty-four (11.5%) isolates had deletions of both AvrLm1 and AvrLm6 and only one of these isolates was collected prior to the breakdown. All 295 isolates were grouped into four genotypic classes (AvrLm1, AvrLm6; AvrLm1, avrLm6; avrLm1, AvrLm6; avrLm1, avrLm6). The frequency of AvrLm1, AvrLm6 isolates was 73.7% prior to the breakdown, but decreased to 37.3% afterwards (Table 3). Conversely, the frequency of avrLm1, avrLm6 isolates was only 0.8% prior to the breakdown, but increased to 28.5% afterwards.

Nine of the 14 isolates harbouring RIP alleles (64%) had a deletion allele at the AvrLm1 locus and all these isolates were cultured from stubble of cultivars with sylvestris resistance. Additionally, all four isolates harbouring the virulent AvrLm6-2 allele (G123C) had a deletion allele at AvrLm1 (Table S3). When the isolates cultured from 2004 onwards were categorised in terms of the stubble from which they were derived, all those cultured from 'sylvestris stubble' had the avrLm1 allele (Table 3) as expected, due to the presence of Rlm1 in these cultivars [17]. Conversely, only 15% of isolates cultured from 'polygenic' stubble, which do not have Rlm1 nor Rlm6, had the avrLm1 allele. The frequency of avrLm6 was 38.7% in isolates cultured from 'polygenic' stubble, compared to 68.7% of isolates cultured from 'sylvestris' stubble (Table 3). For all comparisons of isolates, there were no significant differences in allele frequencies at the mating type locus. Since the mating-type locus is not under selection pressure, a 1:1 ratio of each allele suggests that sampling of isolates has been random (data not shown).

### Table 1. Pathogenicity of Australian isolates of *Leptosphaeria maculans* on cotyledons of *Brassica napus* cultivars Q2 and Columbus and *B. juncea* cv. Aurea.

Cotyledons of 14 day old seedlings were infected with spores of individual isolates. Mean pathogenicity scores (Path. score) were determined by assessing 40 inoculation sites at 17 dpi. Isolates with Path. scores ≤3.9 are classified as avirulent whilst those with Path. scores ≥4.0 are classified as virulent.

*Alleles as described in Table 2.

doi:10.1371/journal.ppat.1001180.t001

---

**Copy of the AvrLm6 locus within isolates harbouring the RIP alleles** (Figure S1). The remaining alleles of AvrLm6 (AvrLm6-1, -2, -3 and -4) harboured single or few nucleotide changes leading to synonymous or amino acid substitutions (G123C, K127E, F54L) compared to isolate v23.1.3 (AvrLm6-0). These amino acid substitutions were generated via non-RIP like mutations (henceforth referred to as non-RIP amino acid substitutions). Isolates harbouring AvrLm6-1, AvrLm6-3 or AvrLm6-4 alleles were avirulent towards cv. Aurea, whilst the four isolates harbouring the AvrLm6-2 allele (G123C) were virulent (Table 1).
Table 2. Alleles of AvrLm1, AvrLm6, LmCys1 and LmCys2 in 295 Australian isolates of *Leptosphaeria maculans*.

Characteristics of the genomic environment of *AvrLm1* and *AvrLm6*

Because of the marked difference in the *AvrLm1* and *AvrLm6* allele frequencies before and after the breakdown of sylvestris resistance, the region flanking these genes was characterised to identify any features that might have influenced allele frequency. A 520 kb AT-rich genomic region bordered by *AvrLm1* and *LmCys2* (Figure 1A) was examined. Part of this region has been described previously in isolate v23.1.3 [8] and includes two additional genes encoding SSPs, *LmCys1* and *LmCys2*. Three other genes, *LmTrans*, *LmGT* and *LmMFS* were present; *LmCys1*, *LmTrans*, *LmGT*, *LmMFS* and *LmCys2* have been reported previously [8,9] but sequence data are only in the form of BAC clones. The features of the proteins are listed below and in Table S4.

The predicted *LmCys1* protein (220 aa) contained eight cysteine residues and its single match was to a ‘secreted in xylem’ Six1 effector (also known as Avr3) of *Fusarium oxysporum* (26% identity, 40% similarity, accession number CAE55870.1) [26]. The predicted *LmCys2* protein (247 aa), also containing eight cysteine residues, had no matches within the NCBI database. Both *LmCys1* and *LmCys2* were predicted to be secreted with signal peptides of 19 and 18 aa, respectively. To determine whether *LmCys1* and *LmCys2* were expressed highly in planta, which would be expected of genes encoding effector-like proteins, quantitative reverse transcriptase PCR (RT-PCR) analyses were performed. Transcript levels of *LmCys1* and *LmCys2* in *plant* were six times higher than those of actin at seven days after inoculation of cotyledons of a susceptible *B. napus* cultivar (Figure 2). *LmCys1* and *LmCys2* were expressed at 0.1 and 0.01 times, respectively, that of actin in seven day *in vitro* cultures. Similar results were obtained with a second isolate (data not shown). This extremely high level of expression in planta compared to *in vitro* is similar to that seen for *AvrLm1* and *AvrLm6* (Figure 2) [8]. These characteristics (small cysteine-rich secreted proteins with no or few matches in databases and high in planta expression) strongly suggested that *LmCys1* and *LmCys2*, like *AvrLm1* and *AvrLm6*, encode effector-like proteins.

The *LmTrans* protein (373 aa) contained a DDE superfamily endonuclease domain predicted to be involved in efficient DNA transposition, and its best match was a putative transposase from *Stagonospora nodorum* (61% identity, 68% similarity, accession number CAD32687.1). The predicted *LmGT* protein (414 aa) was a putative glycosyltransferase with best matches to hypothetical protein PTRG_04076 of *Pyrenophora tritici-repentis* (89% identity, 95% similarity, EDU46914.1). The *LmMFS* protein (591 aa) belonged to the Major Facilitator Superfamily (MFS). This protein had best matches to putative protein SNOG_04897 from *S. nodorum* (74% identity, 82% similarity, EAT87288.2).

**Figure 1.** Location of the genes and non-coding, non-repetitive regions analysed from a 520 kb region of the *Leptosphaeria maculans* genome located on a 2.6 Mb chromosome in isolate v23.1.3. (A) Schematic representation of the *AvrLm1-LmCys2* genomic region whereby highly-repetitive sequences with low GC content (red) flank single copy sections with high GC content (white). Four genes encoding small-secreted proteins, *AvrLm1*, *AvrLm6*, *LmCys1* and *LmCys2*, were sequenced from 295 Australian isolates, whilst the remaining three genes and four non-coding, non-repetitive regions (NC1-4) were sequenced in 84 of the 295 isolates. Repeat-induced point (RIP) mutations were detected in *AvrLm6*, *LmCys1*, *LmTrans* and two non-coding, non-repetitive regions (NC3 and NC4) (black). (B) Location of single-copy sequences relative to the flanking repetitive regions. Within each of the two single copy regions (black) analysed, the frequency of RIP alleles and distribution of RIP mutations decreased in a 5’ to 3’ gradient (arrows). The single copy region (149 bp) between NC3 and *AvrLm6* was not analysed and so the gradient arrow is discontinuous. * denotes a repeat region (620 bp) directly upstream of NC3 that is highly RIP-affected.

doi:10.1371/journal.ppat.1001180.g001
Since *LmCys1* and *LmCys2* had effector-like properties and thus putative roles in the plant-fungal interaction, these genes were sequenced in the 295 isolates. Five and two alleles were detected for *LmCys1* and *LmCys2*, respectively (Table 1), including the wild type alleles obtained from published BAC sequences. RIPCAL analysis showed that only one isolate, which was collected after the breakdown of sylvestris resistance had a RIP allele of *LmCys1*, and there were no deletion alleles, whereas there were no RIP alleles of *LmCys2*, but two isolates collected before breakdown of sylvestris resistance had a deletion of *LmCys2* (Table 1). Overall, the frequencies of individual alleles ranged from 99% for *LmCys2-0* to 0.3% for *AvrLm1-4*. The 295 isolates comprised 34 haplotypes based on alleles of *AvrLm1*, *AvrLm6*, *LmCys1* and *LmCys2* (Table S3).

Four non-coding, non-repetitive regions (Figure 1A) ranging in size between 247 and 657 bp were analysed, to see whether single copy non-coding regions, like the single copy genes, were affected by RIP mutation. These regions and the three other genes *LmTrans*, *LmGT* and *LmMFS* in this region (Figure 1A) were sequenced in a subset of 84 of the 295 isolates, which included isolates representing all 34 haplotypes described above (Table S3). Three, four, 14 and two alleles were detected for *NC1*, *NC2*, *NC3* and *NC4*, respectively, whilst two, one, and three alleles were detected for *LmTrans*, *LmGT* and *LmMFS*, respectively (Table 4 and Table S5). The mutations giving rise to the alleles of *NC1*, *NC2* and *LmMFS* were single non-RIP-like nucleotide substitutions (both synonymous and non-synonymous), and single base pair deletions. No polymorphisms were detected in *LmGT* and no RIP alleles were detected for *NC1*, *NC2*, *LmMFS* or *LmGT*. A single isolate had RIP alleles for *NC4* and *LmTrans* in addition to *NC3*, *AvrLm6* and *LmCys1*. The NC3 region had an extremely high frequency of RIP towards the 3’ end (Figure 3A). The frequency of RIP was higher within the 3’ UTR and the exons, than in the introns and 5’ UTR (Figure 3B). The ten RIP alleles of NC3 and single RIP allele of *LmCys1* showed the highest frequency of RIP at their 5’ ends, whilst RIP mutations were evenly distributed throughout the single RIP allele of *LmTrans* (Figure 2), the latter gene being the furthest 3’ characterised single copy sequence affected by RIP mutation within the *AvrLm1*-*LmCys2* genomic region (Figure 3C). The NC3-*AvrLm6* and *LmCys1-NCA-LmTrans* single copy regions in which RIP mutations were detected, were separated by 37 kb of repetitive elements (Figure 1B). Both these single copy regions were closer to upstream repetitive elements (<342 bp) than to downstream repetitive elements (>1 kb) (Figure 1B). The degree of RIP within these single copy regions was proportional to their proximity to repetitive elements, and thus a gradient of RIP mutations was apparent in a 5’ to 3’ direction (Figures 1B and 3B).

Since amongst these single copy regions the degree of RIP mutations was highest in NC3, a repeat region (620 bp) directly upstream was analysed to see if it was severely RIP-affected and thus might act as a point of ‘leakage’ of RIP into NC3 and *AvrLm6* (Figure 1B). BLAST analysis of the genomic sequence of isolate v23.1.3 revealed 293 copies of this repeat. RIPCAL analysis showed that the repeat directly upstream of NC3 was amongst the most highly RIP-affected copy of that repeat in the genome.

### Transcription of *AvrLm1*, *AvrLm6*, *LmCys1* and *LmCys2* alleles

The mutations of *AvrLm1*, *AvrLm6*, *LmCys1* and *LmCys2* (deletions or RIP mutations including stop codons) would be expected to lead to lack of transcription of these alleles. This hypothesis was assessed in a range of isolates seven days after inoculation of cotyledons of *B. napus* cv. Beacon, which all the isolates could attack. Primers designed to amplify 500–700 bp products within the coding region of these genes were used in end-point RT-PCR (Table 5). Isolates with either *AvrLm1-0* or *AvrLm1-1* allele had an *AvrLm1* transcript of the appropriate size. As expected, isolates with the deletion allele had no transcript. The
AvrLm6-0, AvrLm6-1 or AvrLm6-2 alleles were expressed, whilst the RIP alleles, AvrLm6-6, AvrLm6-7, AvrLm6-8 or AvrLm6-9 were not. As expected, no expression of AvrLm6 or of LmCys2 was detected in isolates with the deletion alleles of these genes. Isolates with LmCys1-0, LmCys1-1 or LmCys1-2 alleles had an LmCys1 transcript, whilst the isolate with the RIP allele, LmCys1-4, did not. Actin transcripts were detected in all isolates.

Rate of mutations of genes
To determine the rates of mutations, genes were analysed by phylogeny-based likelihood ratio tests (LRT) implemented in the program HyPhy [27]. These tests suggested that nucleotides of AvrLm1 and LmMFS mutated at a constant rate, i.e. mutations did not deviate significantly (p = 0.544) from a clock-like rate of evolution. In contrast, an accelerated mutation rate was detected for AvrLm6 and LmCys1 loci (P<0.001) compared to expectations under constant (i.e. clock-like) evolution. However, when RIP alleles were excluded, mutations evolved at a clock-like rate (Table 6). Genetic divergence between haplotypes was calculated using Molecular Evolutionary Genetics Analysis (MEGA) software [28]. Relative rates of sequence evolution of non-RIP alleles were much lower than those of RIP alleles (Table 6). To determine whether the seven proteins were undergoing positive selection, the rates of non-synonymous and synonymous substitutions were compared. All RIP alleles were excluded from this analysis since they contained multiple stop codons. Evolution of codon changes within AvrLm1 and LmCys1 was best explained by a model of positive selection, as shown by a likelihood ratio test implemented using two complementary approaches, the sitewise likelihood-ratio (SLR) and phylogenetic analysis by maximum likelihood (PAML) methods (Table 7). This interpretation was supported by the finding of positive selection at a single codon site in AvrLm1 and at three sites in LmCys1 (Table 7). Analysis of the AvrLm6 protein using the SLR approach suggested a single amino acid (codon 54) may be undergoing positive selection; however, this finding was not supported by the PAML analysis. Similar analyses could not be performed on LmCys2, LmGT or LmTrans as these genes had fewer than three alleles.

Evolution and phylogenetic relationships of RIP and deletion alleles
Two hypotheses for the evolution of RIP alleles, monophyly (having a single origin or having evolved only once) and polyphyly (multiple origins or having evolved several times independently) were tested by comparing tree topologies using the Kishino-Hasegawa (KH) test [29]. For both the Maximum Parsimony (MP) and

**Table 4.** Nucleotide changes in non-coding, non-repetitive regions within the AvrLm1-LmCys2 genomic region in Australian isolates of Leptosphaeria maculans.

| Regiona, b | Allele | Number of isolates (frequency %) | Nucleotide changes | RIP dominance score |
|------------|--------|---------------------------------|-------------------|--------------------|

|            | 7      | 1 (1.2)| 30 | 9 | 7 | 14 (all G to A or C to T) | 1.5 |
|            | 8      | 1 (1.2)| 38 | 13 | 12 | 13 (all G to A or C to T) | 3.6 |
|            | 9      | 1 (1.2)| 34 | 9 | 11 | 14 (all G to A or C to T) | 2.0 |
|            | 10     | 1 (1.2)| 38 | 13 | 11 | 14 (all G to A or C to T) | 3.0 |
|            | 11     | 2 (2.4)| 39 | 9 | 12 | 18 (all G to A or C to T) | 2.1 |
|            | 12     | 3 (3.6)| 40 | 9 | 12 | 19 (all G to A or C to T) | 2.1 |
|            | 13     | 1 (1.2)| 29 | 8 | 8 | 12 (all G to A or C to T) | 1.6 |
| NC4        | 0      | 83 (98.8)| 0 | 0 | 0 | 0 | 0 |
|            | 1      | 1 (1.2)| 9 | 4 | 0 | 5 (all G to A or C to T) | 4.0 |

These isolates represented all 34 haplotypes based on AvrLm1, AvrLm6, LmCys1 and LmCys2 alleles.

The reference sequences are CT485790 (designated as NC1-0), CT485667 (NC2-0), CT485649 (NC3-0) and CT485669 (NC4-0) identified from isolate v23.1.3 [8,9].

The sizes of the amplified products were 517 bp for NC1-0, 496 bp for NC2-0, 657 bp for NC3-0 and 139 bp for NC4-0.

*Leptosphaeria maculans* Avirulence Effectors
PLoS Pathogens | www.plospathogens.org 7 November 2010 | Volume 6 | Issue 11 | e1001180

doi:10.1371/journal.ppat.1001180.004

AvrLm6-0, AvrLm6-1 or AvrLm6-2 alleles were expressed, whilst the RIP alleles, AvrLm6-6, AvrLm6-7, AvrLm6-8 or AvrLm6-9 were not. As expected, no expression of AvrLm6 or of LmCys2 was detected in isolates with the deletion alleles of these genes. Isolates with LmCys1-0, LmCys1-1 or LmCys1-2 alleles had an LmCys1 transcript, whilst the isolate with the RIP allele, LmCys1-4, did not. Actin transcripts were detected in all isolates.

Rate of mutations of genes
To determine the rates of mutations, genes were analysed by phylogeny-based likelihood ratio tests (LRT) implemented in the program HyPhy [27]. These tests suggested that nucleotides of AvrLm1 and LmMFS mutated at a constant rate, i.e. mutations did not deviate significantly (p = 0.544) from a clock-like rate of evolution. In contrast, an accelerated mutation rate was detected for AvrLm6 and LmCys1 loci (P<0.001) compared to expectations under constant (i.e. clock-like) evolution. However, when RIP alleles were excluded, mutations evolved at a clock-like rate (Table 6). Genetic divergence between haplotypes was calculated using Molecular Evolutionary Genetics Analysis (MEGA) software [28]. Relative rates of sequence evolution of non-RIP alleles were much lower than those of RIP alleles (Table 6). To determine whether the seven proteins were undergoing positive selection, the rates of non-synonymous and synonymous substitutions were compared. All RIP alleles were excluded from this analysis since they contained multiple stop codons. Evolution of codon changes within AvrLm1 and LmCys1 was best explained by a model of positive selection, as shown by a likelihood ratio test implemented using two complementary approaches, the sitewise likelihood-ratio (SLR) and phylogenetic analysis by maximum likelihood (PAML) methods (Table 7). This interpretation was supported by the finding of positive selection at a single codon site in AvrLm1 and at three sites in LmCys1 (Table 7). Analysis of the AvrLm6 protein using the SLR approach suggested a single amino acid (codon 54) may be undergoing positive selection; however, this finding was not supported by the PAML analysis. Similar analyses could not be performed on LmCys2, LmGT or LmTrans as these genes had fewer than three alleles.

Evolution and phylogenetic relationships of RIP and deletion alleles
Two hypotheses for the evolution of RIP alleles, monophyly (having a single origin or having evolved only once) and polyphyly (multiple origins or having evolved several times independently) were tested by comparing tree topologies using the Kishino-Hasegawa (KH) test [29]. For both the Maximum Parsimony (MP) and
Maximum Likelihood (ML) approach, trees based on the assumption of a monophyletic origin of RIP alleles performed significantly better than those based on polyphyletic origin (Table 8). The phylogenetic relationship of all detected haplotypes is depicted in Figure 4. The RIP and non-RIP associated alleles form two distinct clusters, supporting the hypothesis of a single origin of RIP alleles. In contrast, haplotypes associated with gene deletions are associated with multiple clades of the tree and have probably arisen several times.

**Discussion**

Selection pressure on frequencies of *AvrLm1* and *AvrLm6* alleles is imposed by extensive sowing of cultivars with *Rlm1* resistance

Breakdown of disease resistance has been observed in other plant fungal pathogen systems where fungal populations evolve rapidly [for review see [30]]. In the canola- *L. maculans* interaction described here, strong selection pressure was exerted on the *AvrLm1* locus, due to extensive sowing of sylvestris cultivars with *Rlm1*, which was consistent with the finding of a rapid increase in the frequency of isolates with virulent (*avrLm1*) alleles after the breakdown of resistance. Surprisingly the frequency of isolates virulent (with the *avrLm6* allele) towards *Rlm6* increased, although cultivars with polygenic or with sylvestris resistance have not been shown to contain *Rlm6* [17,31]. The linkage and genomic location of *AvrLm1* and *AvrLm6* may have led to a selective sweep whereby selection at *AvrLm1* affected the frequency of *avrLm6* alleles through ‘hitchhiking’. Thus strong selection imposed by widespread deployment of a plant resistance gene that favors a complementary effector allele in a pathogen could affect evolution of closely-linked effector genes. It is intriguing that in France recurrent sowing of *Rlm6*-containing cultivars in localised field

---

**Figure 3. Distribution of RIP mutations across the AvrLm1-LmCys2 genomic region in Leptosphaeria maculans.** (A) The ratio of mutated CpA or TpG sites within the seven *AvrLm6* RIP alleles compared to the number of available CpA and TpG nucleotides present in the wild type *AvrLm6*-0 allele over a 100 bp window. Regions where greater than 50% of potential RIP sites are mutated are highlighted in red. There is a higher proportion of RIP mutations towards the 5′ end of the region (3′ end of the *AvrLm6* gene). *AvrLm6*-0, -1, -2, -3 and -4 alleles do not display RIP mutations. (B) The average ratio of RIP mutations within the untranslated regions (UTRs), exons and introns for the seven RIP alleles of *AvrLm6* relative to the number of potential RIP sites in the wild type sequence. The 3′ UTR and exons are undergoing the highest frequency of RIP. (C) The number of RIP alleles for each of the genes and non-coding, non-repetitive (NC) regions analysed across the *AvrLm1-LmCys2* genomic region in 84 isolates (see also Figure S2). The number of RIP alleles is highest for NC3 and decreases in the genes and non-coding regions downstream, consistent with RIP occurring in a directional manner. * represent RIP alleles of *AvrLm6* that are not transcribed and that confer a virulence phenotype on an *Rlm6*-containing cultivar. The remaining RIP alleles of *AvrLm6* were not tested for virulence towards *Rlm6*. doi:10.1371/journal.ppat.1001180.g003
trials led to an increase in avrLm6 isolates and a corresponding increase in isolates avirulent at the AvrLm1 locus [19]. This difference may be due to the different targets of selection pressure - Rlm6 in France and Rlm1 in our study.

This situation whereby selection pressure on one gene affected allele frequencies of another may be partly due to the presence of these two effector genes in a repeat-rich region, where there is a low recombination frequency. Effectors in other fungi are present in repeat-rich regions of the genome of the oomycete, Phytophthora infestans [59]. In the sequenced isolate of L. maculans, AvrLm1 and AvrLm6 are located amongst multiple copies of long terminal repeat retrotransposons, namely Pholy, Olly, Polly and Rolly, which are generally incomplete. Furthermore the distribution and number of these elements within this genomic location varies considerably between isolates [20,22]. The presence of effector genes within such regions is suggested to promote their adaptation and diversification when exposed to strong selection pressure [40]. Rep and Kistler have speculated that the presence of highly repetitive regions containing transposons, may promote mutation of resident effector genes [41].

Table 5. Expression analysis of AvrLm1, AvrLm6, LmCys1 and LmCys2 alleles in Leptosphaeria maculans isolates in planta.

| Isolate | Genotype (allele) | Gene expression (7 days post inoculation) |

Presence of a molecular clock was analysed using a phylogeny-based likelihood ratio test. MEGA was used to infer relative rates of sequence evolution by calculating means of genetic distances (Kimura-2-Parameter (K2P) between haplotypes.

aSince both HyPhy and MEGA approaches are phylogeny-based, a minimum of three distinct alleles are required for analysis. Genes with less than three alleles could not be analysed (NC).

bWhen RIP alleles were excluded from HyPhy analysis (excl. RPs), p values for all genes became non-significant (clock-like).
Repeat-induced point mutations may be 'leaking' from adjacent inactivated transposable elements into single copy regions

The genes and non-coding regions undergoing RIP within the \textit{AvrLm1-LmCys2} gene region are single copy and therefore are not expected to be targeted by RIP. Two explanations for the presence of RIP mutations in these genes are as follows. Firstly, if these genes are the result of an ancestral duplication, RIP mutation may be acting directly on them. However, Fudal et al showed that no closely related paralogs of \textit{AvrLm6} exist in the genome of isolate v23.1.3 suggesting that RIP would not be targeting these sequences due to a duplication event [22]. Alternatively, the \textit{AvrLm6} locus may be completely or partially duplicated in isolates where RIP was detected. However, southern hybridisations suggest only a single copy of the \textit{AvrLm6} locus in isolates where RIP was detected, which does not support the possibility of RIP being targeted to this locus. A more likely explanation is that RIP mutations ‘leak’ from adjacent repetitive sequences. As RIP mutation is traditionally observed to be restricted to repetitive regions and not single copy regions, leakage of RIP mutation might occur within a relatively short distance of a RIP-affected repeat, as suggested by Fudal et al [22]. Indeed, this has been reported in \textit{N. crassa} whereby leakage of RIP was detected in single copy sequences at least 930 bp from the boundary of neighbouring duplicated sequences [42]. This is consistent with our finding of a high frequency of RIP mutations in single copy regions of \textit{L. maculans} with the degree of RIP mutation being proportional to the proximity of flanking repetitive elements. The potential ‘leakage’ of RIP mutations into closely linked effector genes highlights the power of this process to lead to major evolutionary changes to

Kishino-Hasegawa tests were used to assess different hypotheses of RIP evolution by comparing tree topologies as implemented in PAUP*. The probabilities (P) of obtaining better trees were assessed using two-tailed tests, the full optimization criterion and 1000 bootstrap replicates.

*Tree scores refer to branch lengths for the tree topologies. For the maximum likelihood analysis, tree scores are given as –ln of branch length.

**Best** refers to the ‘shortest’ tree, which is likely to be the most accurate.

genes such as effectors that play an important role in the lifestyle of an organism.

Deletion alleles of AvrLm1 and AvrLm6 had multiple origins whilst RIP alleles had a single origin

All haplotypes associated with RIP alleles of AvrLm6 and LmCys1 appeared to have a single origin indicating that the event that led to the RIP occurred only once. Furthermore, haplotypes associated with the virulent AvrLm6-2 allele (cysteine substitution) arose as a single clade. These single origins suggest that events leading to both the RIP mutations and non-RIP amino acid substitutions are much rarer than those leading to the deletion mutations. The RIP event occurred after the break down of sylvestris resistance, as isolates with RIP mutations were not detected before this time. This rapid appearance of RIP mutations is not unprecedented; such mutations have been shown to occur after one generation in L. maculans. When transformants with several tandemly linked copies of a hygromycin resistance gene were crossed with a wild type strain, none of the progeny were resistant to hygromycin due to the presence of multiple stop codons generated by RIP mutations in the hygromycin resistance gene [43].

Mutations associated with resistance toazole fungicides in M. graminicola also are derived from a single origin. Resistance emerged only once following strong selection due to widespread use of azole fungicides [44]. In both the M. graminicola and L. maculans examples, a similar phylogeny was found despite differences in origin and type of evolutionary pressure. In L. maculans haplotypes associated with deletion alleles conferring virulence towards AvrLm1 and AvrLm6 appeared to have a polyphyletic origin. Isolates with these deletions were detected prior to 2004 when the resistance breakdown occurred, albeit at a much lower frequency than afterwards. Haplotypes associated with deletion of both AvrLm1 and AvrLm6 might have been derived directly from the ancestral wild type rather than via the deletion of one gene followed by that of the second.

Deletions, non-synonymous and RIP mutations can confer virulence

Deletions, RIP mutations and non-RIP amino acid substitutions conferred virulence at the AvrLm6 locus, whilst only deletions were responsible for virulence at the AvrLm1 locus. Similar types of mutations were detected in French populations of L. maculans isolates [22]. The finding of a virulence allele of AvrLm6 arising from a non-synonymous, non-RIP like mutation, of a glycine to cysteine substitution, was intriguing. In other avirulence proteins from a non-synonymous, non-RIP like mutation, of a glycine to cysteine substitution, was intriguing. In other avirulence proteins

Materials and Methods

Brassica cultivars and Leptosphaeria maculans isolates

Stubbble of cultivars of B. napus and B. juncea infested with L. maculans was collected each year from 1997 to 2008 from 25 locations across Australia (Table S1). For instance, stubble from a crop sown in 2003 was collected from the field in 2004 and isolates were then cultured from it. Cultivars with ‘polygenic’ resistance (Beacon, Dunkeld, Emblem, Grace, Hyden, Jade, Pinnacle, Skipton, Pinnacle and Tornado TT) had one or more Rlm genes, but none had Rlm1 or Rlm6. The identity of resistance genes in some of these cultivars has been reported [44]. The category of ‘sylvestris resistance’ refers to cultivars (Surpass 400, Surpass 501TT, Surpass 605CL, 45Y77 and 46Y78) with resistance derived from B. napus spp. sylvestris [14] have Rlm1 and RlmS [17]. The category of ‘juncea’ resistance refers to cultivars and lines of B. juncea (cv. Dune and lines JC05002, JC05006 and JC05007). Stubbble of the latter two categories was not collected prior to 2004. From 2003 onwards although cultivars with sylvestris resistance were withdrawn from sale, these lines were grown in yield trials across Australia, and stubble was collected from them. Isolates (287) were cultured from individual ascospores discharged from stubble collected the previous year as described previously [13]. In addition, eight Australian isolates collected in 1987 and 1988 were analysed. All isolates were maintained on 10% Campbell’s V8 juice agar.

Virulence testing

Virulence of a subset of isolates was tested on three B. napus and one B. juncea cultivars. The B. napus cv. Beacon and cv. Q2 are susceptible controls that all isolates could attack. Cultivar Columbus contains Rlm1 and RlmS and B. juncea cv. Aurora contains RlmS and Rlm6 [3]. No Rlm1-only or RlmS-only cultivars were available. Cotyledons of 14-day old seedlings were wounded and inoculated with conidia of individual isolates representing different haplotypes for AvrLm1 and AvrLm6. Symptoms were
assessed at 10, 14 and 17 days post-inoculation (dpi) and pathogenicity scores determined at 17 dpi by scoring lesions on a scale from 0 (no darkening around wounds) to 9 (large grey-green lesions with profuse sporulation). Mean pathogenicity scores (determined from 40 inoculation sites) ≤3.9 were assigned as an avirulent phenotype whilst scores ≥4.0 were assigned as a virulent phenotype [17].

Gene identification and primer design

Non-coding, non-repetitive regions in the AvrLm1-LmCy2 genomic region and genes 3’ of AvrLm6 (Figure 1) were identified using published information [22] and by BLAST searches. Primers were designed upstream and downstream of start and stop codons to allow analysis of the sequences of entire open reading frames. For transcriptional analyses, primers were designed to amplify a 500–700 bp region of the coding sequence, flanking an intron where possible. All primers were designed using the program Primer3 [49] (Table S7). Primers to amplify the mating type locus and actin have been described previously [8,24].

The sequence information for all genes has been deposited in GenBank with the following accession numbers; AvrLm1, AM084345 [1], AvrLm6, AM259336 [2], LmCys1, GU332625, LmTrans, GU332626, LmGT, GU332627, LmMFS, GU332628 and LmCy2, GU332629.

Allele genotyping

Genomic DNA was isolated from mycelia. Conditions for all PCR experiments were 95°C for 3 min; 35 cycles of 95°C for 30 sec, 59°C for 30 sec and 72°C for 1 min; 72°C for 6 min. PCR products were purified using QIAquick PCR purification kit (Qiagen) and sequenced using BigDyeTM terminator cycling conditions. Sequences were analysed using Sequencher v 4.0.5. Deletion genotypes were assigned if no band was produced following amplification with the AvrLm1, AvrLm6 or LmCy2 specific primers. Amplification of the mating type locus was a positive control for DNA quality. In a subset of eight isolates, deletion alleles were confirmed by Southern analysis of genomic DNA that had been digested with HindIII and hybridised with the appropriate probe (Figure S1). Additionally, PCR screens were performed on genomic DNA from two (for LmCy2) to 25 (for AvrLm6) isolates using multiple primer sets that amplify specific regions of the AvrLm1, AvrLm6 and LmCy2 gene regions. These amplifications confirmed that the entire locus was deleted in all isolates tested (data not shown).

Allele sequences were analysed by RIPCAL for the presence of RIP mutations [25]. RIPCAL generates a RIP dominance score, which is the frequency of the dominant dinucleotide RIP mutation (in this case CpA→TpA) relative to the sum of the alternative mutations (CpC→TpC, CpG→TpG and CpT→TpT). Sequences with RIP dominance scores ≥1 are considered to be highly RIP-affected. The ‘model’ sequence used for all RIPCAL analyses was the ‘wild type’ allele (designated with a -θ suffix) from the isolate (v23.1.3) whose genome has been sequenced. The spatial distribution of RIP was assessed for each gene and four non-coding regions by comparing the ratio of mutated CpA or TpG sites detected by RIPCAL, relative to the number of available CpA and TpG nucleotides present within the wild type allele over a 100 bp rolling window.

Expression analysis

Ten infected cotyledons of B. napus cv. Beacon were harvested at 7 dpi. Necrotic tissue surrounding the inoculation wounds of each cotyledon was harvested using a hole punch (diameter 8 mm). Total RNA was purified from this tissue using the RNeasy Plant Mini Kit (Qiagen) and was treated with DNaseI (Invitrogen) before cDNA was synthesized using a first strand cDNA synthesis kit and an oligo-dT primer. End point RT-PCR was used to assess expression of AvrLm1, AvrLm6, LmCys1, LmCy2 and actin.

Quantitative RT-PCR was used to determine levels of expression of AvrLm1, AvrLm6, LmCys1 and LmCy2 in planta and in vitro culture. RNA was prepared from seven day old cultures of isolates with the wild type alleles of these genes, which were growing in 10% V8 juice. Additionally RNA was prepared from cotyledons of B. napus cv. Beacon 7 dpi infected with isolates with the wild type alleles of these genes. Total RNA and cDNA synthesis was performed as described above. Controls lacking reverse transcriptase were included. Quantitative RT-PCR was performed using Rotor-Gene 3000 equipment (Corbett Research, Australia) and QuantiTect SYBR Green PCR kit (Qiagen). A standard curve of amplification efficiency of each gene was generated from purified RT-PCR products [50]. Diluted RT product (1 µl) was added to 19 µl of PCR mix and subjected to 40 cycles of PCR (30 s at 94°C, then 60°C and then 72°C). All samples were analysed in triplicate. The amplified product was detected every cycle at the end of the 72°C step. Melt curve analysis after the cycling confirmed the absence of non-specific products in the reaction. The fluorescence threshold (Ct) values were determined for standards and samples using the Rotor-Gene 5 software. Ct values were exported to Microsoft Excel and analysed [51]. Actin was used as a reference gene.

Phylogenetic analyses

Deviation from a constant rate of molecular evolution within the data sets (i.e. a “molecular clock”) was assessed using the phylogeny-based likelihood ratio test (LRT) implemented in the program HyPhy [27]. To estimate the contribution of the RIP alleles, likelihoods were calculated both for the total data sets and for data sets excluding RIP alleles. MEGA was also used to infer relative rates of sequence evolution by calculating means of genetic distances (Kimura-2-Parameter) between haplotypes.

Evidence for non-neutral evolution was assessed using two complementary approaches by comparing the rate of non-synonymous substitutions with the rate of synonymous substitutions (dn/ds = Ω). Firstly, the analysis was based on the “sitewise likelihood-ratio” method as implemented in the SLR software package [52]. The test consists of performing a likelihood-ratio test on a site-wise basis, testing the null model (neutrality, Ω = 1) against an alternative model Ω ≠ 1 (i.e. purifying selection Ω < 1; positive selection Ω > 1). Secondly, dn/ds = Ω was tested using a phylogenetic analysis based on maximum likelihood as implemented in the PAML software package [53]. Two codon substitution models were compared via likelihood ratio tests (LRT). The comparison included the likelihood estimates of the neutral null model (M7) and the alternative model of positive selection (M8). RIP alleles were excluded from these analyses since such alleles encode sequences with stop codons.

To test different hypotheses of emergence of haplotypes associated with RIP alleles (Table S6), tree topologies using concatenated DNA sequences of all the genes (AvrLm1, AvrLm6, LmCys1, LmTrans, LmGT, LmMFS and LmCy2) and non-coding, non-repetitive regions (NC1-4) were generated and compared using the Kishino-Hasegawa (KH) test [29] as implemented in PAUP* 4.0b 10. Since the RIP mechanism produces the same mutations at specific sites, it is likely that formerly unrelated nucleotide sequences converge, leading to the false impression of similarity due to common descent. To avoid this bias, all CpA to TpA and TpG to TpA nucleotide changes were removed from the data set prior to inferring the phylogentic relationships of
haplotypes. Two alternative hypotheses were then compared; (i) haplotypes containing RIP alleles were monophyletic, i.e. they emerged only once. Trees representing this hypothesis were “constrained” by restricting RIP alleles to cluster only amongst each other (ii) haplotypes containing RIP alleles were polyphyletic, i.e. they emerged several times independently. Trees representing this alternative hypothesis were “unconstrained”, i.e. the pairing of particular alleles in the topology was not restricted. One thousand trees were generated representing each hypothesis, and the probabilities ($P$) of obtaining better trees were assessed using two-tailed tests, the full optimization criterion and 1000 bootstrap replicates. The KH test was conducted for trees constructed under the maximum likelihood and the maximum parsimony criterion.

The phylogenetic relationship among isolates based on the concatenated DNA sequences of all genes and non-coding, non-repetitive regions was assessed by PAUP* using maximum likelihood. Tree searches were conducted with the “fast-stepwise-addition” option and 1000 bootstrap replicates to assess statistical significance of nodes. The GTR-model with estimated substitution-rate matrix was used to evaluate molecular rate constancy.

Supporting Information

Figure S1 Confirmation of deletion alleles for AvrLm1, AvrLm6, and LmCys2 by Southern analysis of genomic DNA. (A) Hybridisation of an AvrLm1 probe to genomic DNA of two isolates that produced an amplicon after PCR using primers specific for AvrLm1 (lanes 1 and 7) and five isolates that did not (lanes 2–6). (B) Hybridisation of an AvrLm6 probe to genomic DNA of five isolates that produced an amplicon after PCR using primers specific for AvrLm6 (lane 1–3 and 7–8) and three isolates that did not (lanes 4–6). (C) Hybridisation of a LmCys2 probe to genomic DNA of a single isolate that produced an amplicon after PCR using primers specific for LmCys2 (lane 1) and one isolate that did not (lane 2). All genomic DNA was digested with HindIII. For three isolates, a 300 bp size difference was observed for genomic DNA fragments hybridising to the AvrLm6 probe. Since no HindIII sites are present in the coding sequence of AvrLm6 the size difference must be due to polymorphisms in HindIII sites outside the region analysed.

Figure S2 Distribution of RIP mutations across the NC3 region, LmCys1 and LmTrans. The ratio of mutated Cpa or TpG sites was compared to the number of Cpa and TpG nucleotides present in the wild type allele over a 100 bp window for the NC3 region (A) and LmCys1 (B) and LmTrans (C) regions. Regions where greater than 50% of potential RIP sites are mutated are highlighted in grey. The gene structure of LmCys1 and LmTrans are represented above the respective graphs.
