Learning and Generalization for Matching Problems

Abstract

We study a classic algorithmic problem through the lens of statistical learning. That is, we consider a matching problem where the input graph is sampled from some distribution. This distribution is unknown to the algorithm; however, an additional graph which is sampled from the same distribution is given during a training phase (preprocessing).

More specifically, the algorithmic problem is to match $k$ out of $n$ items that arrive online to $d$ categories ($d \ll k \ll n$). Our goal is to design a two-stage online algorithm that retains a small subset of items in the first stage which contains an offline matching of maximum weight. We then compute this optimal matching in a second stage.

The added statistical component is that before the online matching process begins, our algorithms learn from a training set consisting of another matching instance drawn from the same unknown distribution. Using this training set, we learn a policy that we apply during the online matching process.

We consider a class of online policies that we term thresholds policies. For this class, we derive uniform convergence results both for the number of retained items and the value of the optimal matching. We show that the number of retained items and the value of the offline optimal matching deviate from their expectation by $O(\sqrt{k})$. This requires usage of less-standard concentration inequalities (standard ones give deviations of $O(\sqrt{n})$). Furthermore, we design an algorithm that outputs the optimal offline solution with high probability while retaining only $O(k \log \log n)$ items in expectation.

1 Introduction

Matching is the bread-and-butter of many real-life problems from the fields of computer science, operations research, game theory, and economics. Some examples include job scheduling where we assign jobs to machines, economic markets where we allocate products to buyers, online advertising where we assign advertisers to ad slots, assigning medical interns to hospitals, and many more.

Let us now discuss a particular motivating example from labor markets in detail. Imagine a firm that is planning a large recruitment. Candidates arrive one-by-one and the HR department immediately decides whether to summon them for an interview. Moreover, the firm has multiple departments, each requiring different skills and having a different target number of hires. Different employees have different subsets of the required skills, and thus fit only certain departments and with a certain quality. The firm’s HR department, following the interviews, decides which candidates to recruit and to which departments to assign them. The HR department has to maximize the total quality of the hired employees such that each department gets its required number of hires with the required skills. In addition, the HR uses data from

the previous recruitment season in order to minimize the number of interviews while not compromising the quality of the solution.

To formulate the example above, we study the following problem. We receive \( n \) items, where each item has a subset of \( d \) properties denoted by \( P_1, \ldots, P_d \). We select \( k \) items out of the \( n \), subject to \( d \) constraints of the form

\[
\text{exactly } k_i \text{ of the selected items must satisfy a property } P_i,
\]

where \( \sum_{i=1}^{d} k_i = k \) and we assume that \( d \ll k \ll n \). Furthermore, if item \( c \) possesses property \( P_i \), then it has a value \( v_i(c) \) associated with this property. Our goal is to compute a matching of maximum value that associates \( k \) items to the \( d \) properties subject to the constraints above.

We consider matching algorithms in the following online setting. Before the matching process begins, there is a preprocessing phase in which the algorithm learns an online policy from a training set. The training set is a single problem instance that consists of \( n \) items drawn independently from an unknown distribution \( D \). Following the preprocessing phase, the algorithm receives an additional \( n \) items online, also drawn independently from \( D \), and uses the learned policy to either reject or retain each item. Finally, the algorithm utilizes the retained items and outputs an (approximately-)optimal feasible solution.

We address the statistical aspects of this problem and develop efficient learning algorithms. In particular, we define a class of thresholds-policies. Each thresholds-policy is a simple rule for deciding whether to retain an item. We present uniform convergence rates for both the number of items retained by a thresholds policy and the value of the resulting solution. We show that these quantities deviate from their expected value by order of \( \sqrt{k} \) (rather than an easier \( \sqrt{n} \) bound; recall that we assume \( k \ll n \)) which we prove using non-trivial concentration inequalities and tools from VC-theory.

Lastly, using these concentration inequalities, we analyze an efficient online algorithm that returns the optimal offline solution with high probability, and retains a near-optimal \( O(k \log \log n) \) number of items in expectation. We show that this is an improvement over a naive greedy algorithm that always returns the optimal solution and retains \( O(k \log n) \) items in expectation while ignoring the training set.

Related work. Celis et al. [2017, 2018] studies similar problems of ranking and voting with fairness constraints. In fact, the optimization problem that they consider allows more general constraints and the value of a candidate is determined from votes/comparisons. The main difference with our framework is that they do not consider a statistical setting (i.e. there is no distribution over the items and no training set for preprocessing) and focus mostly on approximation algorithms for the optimization problem.

Our model is related to the online secretary problem in which one needs to select the best secretary in an online manner (see Ferguson [1989]. Our setting differs from this classical model due to the two-stage process and the complex feasibility constraints. Nonetheless, we remark that there are few works on the secretary model that allow delayed selection (see Vardi [2015], Ezra et al. [2018]) as well as matroid constraints (Babaioff et al. [2007]). These works differ from ours in the way the decision is made, the feasibility constraints and the learning aspect of receiving a single problem instance as a training example.

Another related line of work in algorithmic economics studies the statistical learnability of pricing schemes (see e.g., Morgenstern and Roughgarden [2015, 2016], Hsu et al. [2016], Balcan et al. [2018]). The main difference of these works from ours is that our training set consists of a single “example” (namely the set of items that are used for training), and in their setting (as well as in most typical statistical learning settings) the training set consists of many i.i.d examples. This difference also affects the technical tools used for obtaining generalization bounds. For example, some of our bounds exploit Talagrand’s concentration inequality rather than the more standard Chernoff/McDiarmid/Bernstein inequalities. We note that Talagrand’s inequality and other advanced inequalities were applied in machine learning in the context of learning combinatorial functions (Vondrak [2010], Blum et al. [2017]). See also the survey by Bousquet et al. [2004] or the book by Boucheron et al. [2013] for a more thorough review of concentration inequalities.

Furthermore, there is a large body of work on online matching in which the vertices arrive in various models (see Mehta et al. [2013], Gupta and Molinaro [2016]). We differ from this line of research, by allowing a two-stage algorithm, and requiring to output the optimal matching is the second stage.
2 Our model and results

Let $X$ be a domain of items, where each item $c \in X$ can possess any subset of $d$ properties denoted by $P_1, \ldots, P_d$ (we view $P_i \subseteq X$ as the set of items having property $P_i$). Each item $c$ has a value $v_i(c) \in [0,1]$ associated with each property $P_i$ such that $c \in P_i$.

We are given a set $C \subseteq X$ of $n$ items as well as counts $k_1, \ldots, k_d$ such that $\sum_{i=1}^{d} k_i = k$. Our goal is to select exactly $k$ items in total, constrained on selecting exactly $k_i$ items with property $P_i$. We assume that these constraints are exclusive, in the sense that each item in $C$ can be used to satisfy at most one of the constraints. Formally, a feasible solution is a subset $S \subseteq C$, such that $|S| = k$ and there is partition $S$ into $d$ disjoint subsets $S_1, \ldots, S_d$, such that $S_i \subseteq P_i$ and $|S_i| = k_i$. We aim to compute a feasible subset $S$ that maximizes $\sum_{i=1}^{d} \sum_{c \in S_i} v_i(c)$.

Furthermore, we assume that $d \ll k \ll n$. Namely, the number of constraints is much smaller than the number of items that we have to select, which is much smaller than the total number of items in $C$. In order to avoid feasibility issues we assume that there is a set $C_{\text{dummy}}$ that contains $k$ dummy 0-value items with all the $d$ properties (we assume that the algorithm has always access to $C_{\text{dummy}}$ and do not view them as part of $C$).

The offline problem We first discuss the offline versions of these allocation problems. That is, we assume that $C$ and the capacities $k_i$ are all given as an input before the algorithm starts. We are interested in an algorithm for computing an optimal set $S$. That is a set of items of maximum total value that satisfy the constraints. This problem is equivalent to a maximum matching problem in a bipartite graph $(L,R,E,w)$ defined as follows.

- $L$ is the set of vertices in one side of the bipartite graph. It contains $k$ vertices, where each constraint $i$ is represented by $k_i$ of these vertices.
- $R$ is the set of vertices in the other side of the bipartite graph. It contains a vertex for each item $c \in C$ and for each dummy item $c' \in C_{\text{dummy}}$.
- $E$ is the set of edges. Each vertex in $R$ is connected to each vertex of each of the constraints that it satisfies.
- The weight $w(l,r)$ of edge $(l,r) \in E$ is $v_i(r)$: the value of item $r$ associated with property $P_i$.

There is a natural correspondence between saturated-matchings in this graph, that is matchings in which every $l \in L$ is matched, and between feasible solutions (i.e., solutions that satisfy the constraints) to the allocation problem. Thus, a saturated-matching of maximum value corresponds to an optimal solution. It is well know that the problem of finding such a maximum weight bipartite matching can be solved in polynomial time (see e.g., [Lawler, 2001]).

2.1 Our results

In our work, we consider the following online learning model. We assume that $n$ items are sequentially drawn i.i.d. from an unknown distribution $D$ over $X$. Upon receiving each item, we decide whether to retain it, or reject it irrevocably (the first stage of the algorithm). Thereafter, we select a feasible solution consisting only of retained items (the second stage of the algorithm). Most importantly, before accessing the online sequence and take irreversible online decisions of which items to reject, we have access a training set $C_{\text{train}}$ consisting of $n$ independent draws from $D$. We design online algorithms that use $C_{\text{train}}$ to learn a thresholds-policy $T \in T$ such that with high probability: (i) the number of items that are retained in the online phase is small, and (ii) there is a feasible solution consisting of $k$ retained items whose value is optimal (or close to optimal).

Thresholds-policies are studied in Section 3 and are defined as follows.

\footnote{1In addition to the retained items, the algorithm has access to $C_{\text{dummy}}$.}
Definition 1 (Thresholds-policies). A threshold-policy is parametrized by a vector \( T = (t_1, \ldots, t_d) \) of thresholds, where \( t_i \) corresponds to property \( P_i \) for \( 1 \leq i \leq d \). The semantics of \( T \) is as follows: given a sample \( C \) of \( n \) items, each item \( c \in C \) is retained if and only if there exists a property \( P_i \) satisfied by \( c \), such that its value \( v_i(c) \) passes the threshold \( t_i \). More formally, \( c \) is retained if and only if \( \exists i \in \{1, \ldots, d\} \) such that \( c \in P_i \) and \( v_i(c) \geq t_i \).

Thresholds policies are highly attractive. In fact, the optimal solution in hindsight is a thresholds-policy in itself. This is formalized by the following theorem.

Theorem 2 (Existence of a thresholds-policy that retains an optimal solution). For any set of items \( C \), there exists a thresholds vector \( T \in \mathcal{T} \) that retains exactly \( k \) items that participate in an optimal solution for \( C \).

For a sample \( C \sim D^n \) and a thresholds-policy \( T \in \mathcal{T} \), we denote by \( R_i^T(C) = \{ c : c \in P_i \text{ and } v_i(c) \geq t_i \} \) the set of items that are retained by the threshold \( t_i \), and we denote its expected size by \( \rho_i^T = \text{Ex}_{C \sim D^n}[|R_i^T(C)|] \). Similarly we denote by \( R^T(C) = \bigcup_i R_i^T(C) \) the items retained by \( T \), and by \( \rho^T \) its expectation. We prove that the sizes of \( R_i^T(C) \) and \( R^T(C) \) are concentrated around their expectations uniformly for all thresholds policies.

Theorem 3 (Uniform convergence of the total number of retained items). With probability at least \( 1 - \delta \) over \( C \sim D^n \), the following holds for all policies \( T \in \mathcal{T} \) simultaneously:

1. If \( \rho^T \geq k \), then \( (1 - \epsilon)\rho^T \leq |R^T(C)| \leq (1 + \epsilon)\rho^T \), and
2. If \( \rho^T < k \), then \( \rho^T - \epsilon k \leq |R^T(C)| \leq \rho^T + \epsilon k \),

where
\[
\epsilon = O\left(\sqrt{d \log(d) \log(n/k) + \log(1/\delta)} \right).
\]

Theorem 4 (Uniform convergence of the number of retained items per constraint). With probability at least \( 1 - \delta \) over \( C \sim D^n \), the following holds for all policies \( T \in \mathcal{T} \) and all \( i \leq d \) simultaneously:

1. If \( \rho_i^T \geq k \), then \( (1 - \epsilon)\rho_i^T \leq |R_i^T(C)| \leq (1 + \epsilon)\rho_i^T \), and
2. If \( \rho_i^T < k \), then \( \rho_i^T - \epsilon k \leq |R_i^T(C)| \leq \rho_i^T + \epsilon k \),

where
\[
\epsilon = O\left(\sqrt{\log(d) \log(n/k) + \log(1/\delta)} \right).
\]

Furthermore, we denote by \( V^T(C) \) the value of the optimal solution among the items retained by the thresholds-policy \( T \), and we denote its expectation by \( v^T = \text{Ex}_{C \sim D^n}[V^T(C)] \). We show that \( V^T(C) \) is also concentrated uniformly for all thresholds policies.

Theorem 5 (Uniform convergence of values). With probability at least \( 1 - \delta \) over \( C \sim D^n \), the following holds for all policies \( T \in \mathcal{T} \) simultaneously:

\[
|v^T - V^T(C)| \leq \epsilon k, \text{ where } \epsilon = O\left(\sqrt{d \log k + \log(1/\delta)} \right).
\]

We note that a bound of \( \tilde{O}(\sqrt{n}) \) (rather than \( O(\sqrt{k}) \)) on the additive deviation of \( V^T(C) \) from its expectation can be derived using the McDiarmid’s inequality [McDiarmid, 1989]. However, this bound is meaningless when \( \sqrt{n} > k \) (because \( k \) upper bounds the value of the optimal solution). We use Talagrand’s
concentration inequality [Talagrand, 1995] to derive the $O(\sqrt{k})$ upper bound on the additive deviation. Talagrand’s concentration inequality allows us to utilize the fact that an optimal solution uses only $k \ll n$ items, and therefore replacing an item that does not participate in the solution does not affect its value.

We next use these uniform convergence results to design our learning algorithms. In Section 4 we prove the following.

**Theorem 6.** There exists an algorithm that learns a thresholds-policy $T$ from a single training sample $C_{\text{train}} \sim D^n$, such that when processing online the “test sample” $C \sim D^n$ using $T$, then

- It outputs an optimal solution with probability at least $1 - \delta$.
- Its expected number of retained items in the first phase is $O\left(k(\log d + \log \log(n/k) + \log \log(1/\delta))\right)$.

We compare this result to an oblivious greedy online algorithm that ignores the training set. In the first phase, this greedy algorithm acts greedily by keeping an item if it participates in the best solution thus far. In the second phase, the algorithm computes an optimal matching among the retained items. We have the following guarantee for this greedy algorithm proven in Appendix A.1.

**Theorem 7.** The greedy algorithm always outputs the optimal solution and retains $O(k \log(n/k))$ items in expectation.

Thus, with the additional information given by the training set, the algorithm presented in Theorem 6 improves the dependence $n$ from $\log(n/k)$ to $\log \log(n/k)$.

Finally, in Section 5 we show a lower bound implying that our algorithm is nearly-optimal in the following sense.

**Theorem 8.** Consider the case where $k = d$ and $k_1 \cdots k_d = 1$. There exists a universe $X$ and a distribution $D$ over $X$ such that for $C \sim D^n$ the following holds: Any online learning algorithm that retains a subset $S \subseteq C$ of items that contains an optimal solution must satisfy that $\mathbb{E}[|S|] = \Omega(k \log \log(n/k))$.

3 Thresholds-policies

We next discuss a framework to design algorithms that exploit the training set to learn policies that are applied in the first phase of the matching process. We would like to frame this in standard ML formalism by phrasing this problem as learning a class $H$ of policies such that:

- $H$ is not too small: The policies in $H$ should yield solutions with high values (optimal, or near-optimal).
- $H$ is not too large: $H$ should satisfy some uniform convergence properties; i.e. the performance of each policy in $H$ on the training set is close, with high probability, to its expected real-time performance on the sampled items during the online selection process.

Indeed, as we now show these demands are met by the class $T$ of thresholds policies (Definition 1). We first show that the class of thresholds-policies contains an optimal policy, and in the sequel we show that it satisfies attractive uniform convergence properties.

An assumption (values are unique). We assume that for each constraint $P_i$, the marginal distribution over the value of $c \sim D$ conditioned on $c \in P_i$ is atomless; namely $\Pr_{c \sim D}[v(c) = v \mid c \in P_i] = 0$ for every $v \in [0,1]$. This assumption can be removed by adding artificial tie-breaking rules, but making it will simplify some of the technical statements.

**Theorem** (There is a thresholds policy that retains an optimal solution – restatement of Theorem 2). For any set of items $C$, there exists a thresholds vector $T \in T$ that retains exactly $k$ items that form an optimal solution for $C$. 

Proof. Let $S$ denote the set of $k$ items in an optimal solution for $C$, and let $S_i \subseteq S \cap P_i$ be the subset of $M$ that is assigned to the constraint $P_i$. Define $t_i = \min_{c \in S_i} v_i(c)$, for $i \geq 1$. Clearly, $T$ retains all the items in $S$. Assume towards contradiction that $T$ retains an item $c_j \notin S$, and assume that $P_i$ is a constraint such that $c_j \in P_i$ and $v_i(c_j) \geq t_i$. Since by our assumption on $D$ all the values $v_i(c_j)$ are distinct it follows that $v_i(c_j) > t_i$. Thus, we can modify $S$ by replacing $c_j$ with the item of minimum value in $S_i$ and increase the total value. This contradicts the optimality of $S$. \hfill $\square$

We next establish generalization bounds for the class of thresholds-policies.

### 3.1 Uniform convergence of the number of retained items

The following theorems establish uniform convergence results for the number of retained items. Namely, with high probability we have $R_i^{T} \approx \rho_i^{T}$, $R^{T} \approx \rho^{T}$ simultaneously for all $T \in T$ and $i \leq d$.

**Theorem** (Uniform convergence of the number of retained items – restatement of Theorem 3). With probability at least $1 - \delta$ over $C \sim D^n$, the following holds for all policies $T \in T$ simultaneously:

1. If $\rho^{T} \geq k$, then $(1 - \epsilon)\rho^{T} \leq |R^{T}(C)| \leq (1 + \epsilon)\rho^{T}$, and

2. if $\rho^{T} < k$, then $\rho^{T} - \epsilon k \leq |R^{T}(C)| \leq \rho^{T} + \epsilon k$,

where

$$
\epsilon = O\left(\sqrt{\frac{d \log(d) \log(n/k) + \log(1/\delta)}{k}}\right).
$$

**Theorem** (Uniform convergence of the number of retained items per constraint – restatement of Theorem 4). With probability at least $1 - \delta$ over $C \sim D^n$, the following holds for all policies $T \in T$ and all $i \leq d + 1$ simultaneously:

1. If $\rho_i^{T} \geq k$, then $(1 - \epsilon)\rho_i^{T} \leq |R_i^{T}(C)| \leq (1 + \epsilon)\rho_i^{T}$, and

2. if $\rho_i^{T} < k$, then $\rho_i^{T} - \epsilon k \leq |R_i^{T}(C)| \leq \rho_i^{T} + \epsilon k$,

where

$$
\epsilon = O\left(\sqrt{\frac{\log(d) \log(n/k) + \log(1/\delta)}{k}}\right).
$$

The proofs of Theorem 3 and Theorem 4 are based on standard VC-based uniform convergence results, and technically the proof boils down to bounding the VC-dimension of the families

$$
\mathcal{R} = \{R^{T} : T \in T\} \quad \text{and} \quad Q = \{R_i^{T} : T \in T, \ i \leq d\}.
$$

**Technical notation.** For $m \in \mathbb{N}$, the set $\{1, \ldots, m\}$ is denoted by $[m]$. Given a family of sets $F$ over a domain $X$, and $Y \subseteq X$, the family $\{f \cap Y : f \in F\}$ is denoted by $F|_Y$. Recall that the VC dimension of $F$ is the maximum size of $Y \subseteq X$ such that $F|_Y$ contains all subsets of $Y$.

**Lemma 9.** $\text{VC}($\mathcal{R}$) = O(d \log d)$.

**Proof.** Let $S$ be a set of items shattered by $\mathcal{R}$ and denote its size by $m$; since $S$ is arbitrary, an upper bound on $m$ implies an upper bound on $\text{VC}(\mathcal{R})$. To this end we upper bound the number of subsets in $\mathcal{R}|_S = \{S \cap R_T : R_T \in \mathcal{R}\}$. Now, there are $m$ items in $S$ with at most $m$ different values. Therefore, we can restrict our attention to thresholds-policies where each threshold is picked from a fixed set of $m + 1$ meaningful locations (one location in between values of two consecutive items when we sort the items by value). Thus $|\mathcal{R}|_S \leq (m + 1)^d$, but, as $S$ is shattered, $|\mathcal{R}|_S = 2^m$ and we get $m \leq d \log_2(m + 1)$. This implies $m = O(d \log d)$ from which we conclude that $\text{VC}(\mathcal{R}) = O(d \log d)$. \hfill $\square$
Lemma 10. \( \text{VC}(Q) = O(\log d) \).

Proof. For \( i \leq d, \) let \( Q_i = \{ R^T : T \in T \} \). Note that \( Q = \bigcup_i Q_i \). We claim that \( \text{VC}(Q_i) = 1 \) for all \( i \). Indeed, let \( c', c'' \) be two items. Note that if \( c' \notin P_i \) or \( c'' \notin P_i \) then \( \{c', c''\} \) is not contained by \( Q_i \) and therefore not shattered by it. Therefore, assume that \( c', c'' \in P_i \) and \( v_i(c') \geq v_i(c'') \). Now, it follows that any threshold \( T \) that retains \( c'' \) must also retain \( c' \), and so it follows that also in this case \( \{c', c''\} \) is not shattered.

The bound on the VC dimension of \( Q = \bigcup_{i \leq d} Q_i \) follows from the next lemma.

Lemma 11. Let \( m \geq 2 \) and let \( F_1, \ldots, F_m \) be classes with VC dimension at most 1. Then, the VC dimension of \( \bigcup_i F_i \) is at most \( 10 \log m \).

Proof. We show that \( \bigcup_i F_i \) does not shatter a set of size \( 10 \log m \). Let \( Y \subseteq X \) of size \( 10 \log m \). Indeed, by the Sauer’s Lemma [Sauer, 1972]:

\[
|\{(\cup_i F_i)|_Y\}| \leq m \left( \binom{10 \log m}{0} + \binom{10 \log m}{1} \right) = m(1 + 10 \log m) < m^{10} = 2^{10 \log m},
\]

and therefore, \( Y \) is not shattered by \( \bigcup_i F_i \).

This finishes the proof of Lemma 10.

Using Lemma 9, we can now apply standard uniform convergence results from VC-theory to derive Theorem 3 and Theorem 4.

Definition 12 (Relative \((p, \epsilon)\)-approximation; [Har-Peled and Sharir, 2011]). Let \( \mathcal{F} \) be a family of subsets over a domain \( X \), and let \( \mu \) be a distribution on \( X \). \( Z \subseteq X \) is a \((p, \epsilon)\)-approximation for \( \mathcal{F} \) if for each \( f \in \mathcal{F} \) we have,

1. If \( \mu(f) \geq p \), then \((1 - \epsilon)\mu(f) \leq \mu(f) \leq (1 + \epsilon)\mu(f)\),
2. If \( \mu(f) < p \), then \( \mu(f) - \epsilon p \leq \mu(f) \leq \mu(f) + \epsilon p \),

where \( \mu(f) = |Z \cap f|/|Z| \) is the (“empirical”) measure of \( f \) with respect to \( Z \).

The proof of Theorems 3 and 4 now follows by plugging \( p = k/n \) in [Har-Peled and Sharir, 2011, Theorem 2.11], which we state in the next proposition.

Proposition 13 (Har-Peled and Sharir, 2011). Let \( \mathcal{F} \) and \( \mu \) like in Definition 12. Suppose \( \mathcal{F} \) has VC dimension \( m \). Then, with probability at least \( 1 - \delta \), a random sample of size \( \Omega \left( \frac{m \log(1/p) + \log(1/\delta)}{\epsilon^2 p} \right) \) is a relative \((p, \epsilon)\)-approximation for \( \mathcal{F} \).

3.2 Uniform convergence of values

We now prove a concentration result for the value of an optimal solution among the retained items. Unlike the number of retained items, the value of an optimal solution corresponds to a more complex random variable, and analyzing the concentration of its empirical estimate requires more advanced techniques. We prove the following concentration result for this random variable.

Theorem (Uniform convergence of values - restatement of Theorem 5). With probability at least \( 1 - \delta \) over \( C \sim D^n \), the following holds for all policies \( T \in T \) simultaneously:

\[
|V_T - V_T(C)| \leq \epsilon k, \text{ where } \epsilon = O \left( \sqrt{\frac{d \log k + \log(1/\delta)}{k}} \right).
\]
Note that unlike most uniform convergence results that guarantee simultaneous convergence of empirical averages to expectations, here $V^T(C)$ is not an average of the $n$ samples, but rather a more complicated function of them. To prove the theorem we need the following concentration inequality for the value of the optimal selection in hindsight. Note that by Theorem 2 this value equals to $V^T(C)$ for some $T$.

**Lemma 14.** Let $\text{OPT}(C)$ denote the value of the optimal solution for a sample $C$. We have that $$\Pr_{C \sim D^n}\left[|\text{OPT}(C) - \text{Ex}[\text{OPT}(C)]| \geq \alpha\right] \leq 2 \exp(-\alpha^2/2k).$$

So, for example, it happens that $|\text{OPT}(C) - \text{Ex}[\text{OPT}(C)]| \leq \sqrt{2k \log(2/\delta)}$ with probability at least $1 - \delta$.

To prove this lemma we use the following version of Talagrand’s inequality (that appears for example in lecture notes by van Handel [2014]).

**Proposition 15** (Talagrand’s Concentration Inequality). Let $f : \mathbb{R}^n \mapsto \mathbb{R}$ be a function, and suppose that there exist $g_1, \ldots, g_n : \mathbb{R}^n \mapsto \mathbb{R}$ such that for any $x, y \in \mathbb{R}^n$

$$f(x) - f(y) \leq \sum_{i=1}^n g_i(x)1_{[x_i \neq y_i]}.$$  

Then, for independent random variables $X = (X_1, \ldots, X_n)$ we have

$$\Pr[|f(X) - \text{Ex}[f(X)]| > \alpha] \leq 2 \exp\left(-\frac{\alpha^2}{2 \sup_{x} \sum_{i=1}^n g_i^2(x)}\right).$$

**Proof of Lemma 14**. We apply Talagrand’s concentration inequality to the random variable $\text{OPT}(C)$. Our $X_i$’s are the items $c_1, \ldots, c_n$ in the order that they are given. We show that Eq. (I) holds for $g_i(C) = 1_{[c_i \in S]}$ where $S = S(C)$ is a fixed optimal solution for $C$ (we use some arbitrary tie breaking among optimal solutions). We then have, $\sum_{i=1}^n g_i^2(C) = |S| = k$, thus completing the proof.

Now, let $C, C'$ be two samples of $n$ items. Recall that we need to show that

$$\text{OPT}(C) - \text{OPT}(C') \leq \sum_{i=1}^n g_i(C)1_{[c_i \neq c'_i]}.$$  

We use $S$ to construct a solution $S'$ for $C'$ as follows. Let $S_j \subseteq S$ the subset of $S$ matched to $P_j$. For each $i$, if $c_i \in S_j$ for some $j$, and $c_i = c'_j$, then we add $i$ to $S'_j$. Otherwise, we add a dummy item from $C'_{\text{dummy}}$ to $S'_j$ (with value zero). Let $V(S')$ denote the value of $S'$. Note that the difference between the values of $S$ and $S'$ is the total value of all items $i \in S$ such that $c_i \neq c'_i$. Since the item values are bounded in $[0, 1]$ we get that

$$\text{OPT}(C) - V(S') = \sum_{j=1}^d \sum_{c_i \in S_j} v_j(c_i)1_{[c_i \neq c'_i]} \leq \sum_{j=1}^d \sum_{c_i \in S_j} 1_{[c_i \neq c'_i]} = \sum_{i=1}^n g_i(C)1_{[c_i \neq c'_i]}.$$  

The proof is complete by noticing that $\text{OPT}(C') \geq V(S')$.

We also require the following construction of a bracketing of $T$ which is formally presented in Appendix A.2

**Lemma 16.** There exists a collection of $\mathcal{N}$ thresholds-policies such that $|\mathcal{N}| \leq k^{O(d)}$, and for every thresholds-policy $T \in \mathcal{T}$ there are $T^+, T^- \in \mathcal{N}$ such that

1. $V^{T^+}(C) \leq V^T(C) \leq V^{T^-}(C)$ for every sample of items $C$; note that by taking expectations this implies that $v^{T^+} \leq v^T \leq v^{T^-}$, and
2. $v^{T^+} - v^{T^-} \leq 10.$
Proof of Theorem 3 The items in C that are retained by T are independent samples from a distribution D' that is sampled as follows: (i) sample c ∼ D, and (ii) if c is retained by T then keep it, and otherwise discard it. This means that v^T(C) is in fact the optimal solution of C with respect to D'. Since Lemma 14 applies to every distribution D we can apply it to D' and get that for any fixed T ∈ T

\[ \Pr_{c \sim D}[|v^T - V^T(C)| \geq \alpha] \leq 2 \exp(-\alpha^2/2k). \]

Now, by the union bound for \( N \) be as in Lemma 16 we get that the probability that there is \( T \in N \) such that \( |v^T - V^T(C)| \geq \alpha \) is at most \( |N| \cdot 2 \exp(-\alpha^2/2k). \) Thus, since \( |N| \leq k^{O(d)} \), it follows that with probability at least \( 1 - \delta \),

\[ (\forall T \in N): |v^T - V^T(C)| \leq O\left(\sqrt{k(d \log k + \log(1/\delta))}\right). \] (2)

We now show why uniform convergence for \( N \) implies uniform convergence for \( T \). Combining Lemma 16 with Equation (2) we get that with probability at least \( 1 - \delta \), every \( T \in T \) satisfies:

\[ |v^T - V^T(C)| \leq \max\{|v^{T^+} - V^{T^+}(C)|, |v^{T^-} - V^{T^-}(C)|\} \quad \text{by Item 1 of Lemma 16} \]
\[ \leq \max\{|v^{T^+} - V^{T^+}(C)|, |v^{T^-} - V^{T^-}(C)|\} + 10 \quad \text{by Item 2 of Lemma 16} \]
\[ \leq 10 + O\left(\sqrt{k(d \log k + \log(1/\delta))}\right) \quad \text{(by Eq. (2))} \]

Here the first inequality follows from Item 1 by noticing that if \([a, b], [c, d]\) are intervals on the real line and \( x \in [a, b], y \in [c, d] \) then \( |x - y| \leq \max\{|b - c|, |d - a|\} \), and plugging in \( x = v^T, y = V^T(C), a = v^T, b = v^{T^+}, c = V^{T^-}(C), d = V^{T^+}(C) \).

This finishes the proof, by setting \( \epsilon \) such that \( \epsilon \cdot k = O\left(\sqrt{k(d \log k + \log(1/\delta))}\right) \).

\[ \square \]

4 Algorithms based on learning thresholds-policies

We next exemplify how one can use the above properties of thresholds-policies to design algorithms. A natural algorithm would be to use the training set to learn a threshold-policy \( T \) that retains an optimal solution with \( k \) items from the training set as specified in Theorem 2 and then use this online policy to retain a subset of the \( n \) items in the first phase. Theorem 3 and Theorem 5 imply that with probability \( 1 - \delta \), the number of retained items is at most \( m = k + O\left(\sqrt{kd \log(d) \log(n/k) + k \log(1/\delta)}\right) \) and that the value of the resulting solution is at least \( \text{OPT} - O\left(\sqrt{kd \log k + k \log(1/\delta)}\right) \).

We can improve this algorithm by combining it with the greedy algorithm of Theorem 7 described in Appendix A.1. During the first phase, we retain an item \( c \) only if (i) \( c \) is retained by \( T \), and (ii) \( c \) participates in the optimal solution among the items that were retained thus far. Theorem 7 then implies that out of these \( m \) items greedy keeps a subset of

\[ O\left(k \log \frac{m}{k}\right) = O\left(k \log \log \left(\frac{m}{k}\right) + \log \log \left(\frac{1}{\delta}\right)\right), \]

items in expectation that still contains a solution of value at least \( \text{OPT} - O\left(\sqrt{kd \log k + k \log(1/\delta)}\right) \).

We can further improve the value of the solution and guarantee that it will be optimal (with respect to all \( n \) items) with probability \( 1 - \delta \). This is based on the observation that if the set of retained items contains the top \( k \) items of each property \( P_i \) then it also contains an optimal solution. Thus, we can compute a thresholds-policy \( T \) that retains the top \( k + O\left(\sqrt{kd \log(d) \log(n/k) + k \log(1/\delta)}\right) \) items of each property from the training set (if the training set does not have this many items with some property then set the corresponding threshold to 0). Then, it follows from Theorem 4 that with probability \( 1 - \delta \), \( T \) will retain the top \( k \) items of each property in the first online phase and therefore will retain an optimal solution. Now, Theorem 4 implies that with probability \( 1 - \delta \) the total number of items that are retained by \( T \) in real-time is at most
\[ m = dk + O(d \sqrt{k \log(n/k) \log(\delta)}). \] By filtering the retained elements with the greedy algorithm of Theorem 7 as before it follows that the total number of retained items is at most
\[ k + k \log \left( \frac{m}{k} \right) = O \left( k \left( \log d + \log \log \left( \frac{n}{k} \right) + \log \log \left( \frac{1}{\delta} \right) \right) \right) \]
with probably \( 1 - \delta \). This proves Theorem 8.

## 5 A lower bound

In the previous section we have presented an algorithm that with probability at least \( 1 - \delta \) outputs an optimal solution while retaining at most \( O(k \log n + \log d + \log(1/\delta)) \) items in expectation during the first phase.

We now present a proof of Theorem 8. We start with the following lemma that shows the dependence on \( \delta \) cannot be improved in general, even for \( k = 1 \), when there are no constraints, and the distribution over the items is known to the algorithm (so there is no need to train it on a sample from the distribution):

**Lemma 17.** Let \( v_1, \ldots, v_n \in [0, 1] \) be drawn uniformly and independently, let \( e^{-n/2} < \delta < 1/10 \) and let \( A \) be an algorithm that retains the maximal value among the \( v_i \)'s with probability at least \( 1 - \delta \). Then,
\[ \text{Ex}[ |S| ] = \Omega \left( \log \log \left( \frac{1}{\delta} \right) \right), \]
where \( S \) is the set of values retained by the algorithm.

Thus, it follows that for \( \delta = \text{poly}(1/n) \) and \( k, d = O(1) \) the bound in Theorem 8 is tight.

**Proof.** Define \( \alpha = \frac{\ln(1/\delta)}{2n} \in (1/n, 1/4) \). Let \( E_i \) denote the event that \( v_i \geq 1 - \alpha \) and is the largest among \( v_1, \ldots, v_i \). We have that
\[ \text{Ex}[ |S| ] \geq \sum_i \Pr[ \text{v}_i \text{ is picked and } E_i ] = \sum_i (\Pr[ E_i ] - \Pr[ v_i \text{ is rejected and } E_i ]). \] (3)

We show that since \( A \) errs with probability at most \( \delta \) then \( \sum \Pr[ E_i \text{ and } v_i \text{ is rejected} ] \) is small.

\[
\delta \geq \Pr[ A \text{ rejects } v_{\text{max}} ] \geq \sum_i \Pr[ A \text{ rejects } v_i \text{ and } E_i \text{ and } v_i = v_{\text{max}} ] \\
= \sum_i \Pr[ v_i = v_{\text{max}} \mid A \text{ rejects } v_i \text{ and } E_i ] \cdot \Pr[ A \text{ rejects } v_i \text{ and } E_i ] \\
\geq \sum_i \Pr[ v_i \leq 1 - \alpha \text{ for all } i > t \mid A \text{ rejects } v_i \text{ and } E_i ] \cdot \Pr[ A \text{ rejects } v_i \text{ and } E_i ] \\
= \sum_i \Pr[ v_i \leq 1 - \alpha \text{ for all } i > t ] \cdot \Pr[ A \text{ rejects } v_i \text{ and } E_i ] \\
\geq \left( 1 - \alpha \right)^{n-t} \sum_i \Pr[ A \text{ rejects } v_i \text{ and } E_i ].
\]
The crucial part of the above derivation is in third line. It replaces the event “\( v_i = v_{\text{max}} \)” by the event “\( v_i \leq 1 - \alpha \text{ for all } i > t \)” (which is contained in the event “\( v_i = v_{\text{max}} \)” under the above conditioning). The gain is that the events “\( v_i \leq 1 - \alpha \text{ for all } i > t \)” and “\( A \text{ rejects } v_i \text{ and } E_i \)” are independent (the first depends only on \( v_i \) for \( i > t \) and the latter on \( v_i \) for \( i \leq t \)). This justifies the “\( = \)” in the fourth line.
Rearranging, we have $\sum_i \Pr[A \text{ rejects } v_i \text{ and } E_i] \leq \frac{\delta}{(1-\alpha)^2}$. Substituting this bound in Eq. (3),

$$\Pr[|S|] \geq \sum_i \Pr[v_i \text{ is picked and } E_i] = \sum_i (\Pr[E_i] - \Pr[v_i \text{ is rejected and } E_i]) = \sum_i \Pr[E_i] - \frac{\delta}{(1-\alpha)^2} \geq \frac{1}{4} \ln(\alpha n) - \delta \cdot \exp(2\alpha n)$$

(explained below)

$$= \frac{1}{4} \ln \left( \frac{\ln(1/\delta)}{2} \right) - \delta \exp(\ln(1/\delta))$$

(by the definition of $\alpha$)

$$= \frac{1}{4} \ln \ln(1/\delta) - \frac{1}{4} \ln 2 - 1 = \Omega(\log \log(1/\delta)),$$

which is what we needed to prove. The last inequality follows because

(i) $\sum_i \Pr[E_i] \geq \frac{1}{4} \ln(\alpha n)$ (as is explained next), and

(ii) $1 - \alpha \geq \exp(-2\alpha)$ for every $\alpha \in [0, \frac{1}{4}]$ (which can be verified using basic analysis).

To see (i), note that

$$\sum_i \Pr[E_i] = \mathbb{E} \left[ \sum_i 1_{E_i} \right].$$

Let $z = \left| \{t : v_t \geq 1 - \alpha \} \right|$. Since the $v_t$’s are uniform in $[0, 1]$ then by the same argument as in the proof of Lemma 19 we get that

$$\mathbb{E} \left[ \sum_i 1_{E_i} \mid z \right] = \sum_{i=1}^{z} \frac{1}{i} \geq \int_{1}^{z+1} \frac{1}{x} = \ln(z+1),$$

and therefore

$$\mathbb{E} \left[ \sum_i 1_{E_i} \right] = \mathbb{E} \mathbb{E} \left[ \sum_i 1_{E_i} \mid z \right] \geq \mathbb{E} \left[ \ln(z+1) \right].$$

Let $Z \sim \text{Bin}(n, \alpha)$, and therefore we need to lower bound $\mathbb{E}[\ln(Z+1)]$ for $Z \sim \text{Bin}(n, \alpha)$. To this end, we use the assumption that $\alpha > 1/n$, and therefore $\Pr[Z \geq \alpha \cdot n] \geq 1/4$ (see Greenberg and Mohri, 2013 for a proof of this basic fact). In particular, this implies that $\mathbb{E}[\ln(Z+1)] \geq \frac{1}{4} \ln(\alpha n + 1) > \frac{1}{4} \ln(\alpha n)$, which finishes the proof.

Lemma 17 implies Theorem 8 as follows: set $k = d$, $k_1 = \cdots = k_d = 1$, $\delta = k/2n$, and $n \geq 100k$. Pick a distribution $D$ which is uniform over items, each satisfying exactly one of $d$ properties, and with value drawn uniformly from $[0, 1]$.

It suffices to show that with probability of at least 1/3, the algorithm retains an expected number of $\Omega(\log \log(n/k))$ items from a constant fraction, say 1/4, of the properties $i$. This follows from Lemma 17 as we argue next. Let $n_i$ denote the number of observed items of property $i$. Then, since $\mathbb{E}[n_i] = n/d = n/k \geq 100$, the multiplicative Chernoff bound implies that $n_i \geq n/2k$ with high probability (probability = 1/2 suffices). Therefore, the expected number of properties $i$’s for which $n_i \geq n/2k$ is at least $k/2$. Now, consider the random variable $Y$ which counts for how many properties $i$ we have $n_i \geq n/2k$. Since $Y$ is at most $k$ and $E(Y) \geq k/2$, then a simple averaging argument implies that with probability of at least 1/3 we have that $Y \geq k/4$. Conditioning on this event (which happens with probability $\geq 1/3$), Lemma 17 implies that $\mathbb{E}[|S_i|] = \Omega(\log \log(n/k))$ for each of these $i$’s.

\footnote{Note that to apply Lemma 17 on $S_i$ we need $\delta > e^{-n_i/2}$, which is equivalent to $n_i > 2 \ln(1/\delta)$.}

A Deferred Proofs

A.1 The Greedy Online Algorithm

A simple way to collect a small set of items that contains the optimal solution is to select the $k$ largest items of each property. This set clearly contains the optimal solution. A simple argument, as in the proof of Lemma 19, shows that this implementation of the first stage keeps $O(kd \log n/k)$ items on average. In the following we present a greedy algorithm that retains an average number of $O(k \log n/k)$ items in the first phase.

The greedy algorithm works as follows: when we process the $i$’th item, $c_i$, the algorithm computes the optimal solution $M_i$ of the first $i$ items (recall that we assume the algorithm has access to $C_{\text{dummy}}$, a large enough pool of zero valued items so there is always a feasible solution). The greedy algorithm retains $c_i$ if and only if $c_i$ participates in $M_i$. We assume that $M_i$ is unique for every $i$ (we can achieve this with an arbitrary consistent tie breaking rule, say among matchings of the same value we prefer the one that maximizes the sum of the indices of the matched items.). Since the optimal solutions correspond to maximum-weighted bipartite-matchings between the items and the constraints, we have the following lemma.

Lemma 18. The optimal solution, denoted by $M$, is a subset of the retained items.

Proof. Consider an item $c$ matched by $M$ and assume by contradiction that $c$ is not matched in $M_i$. Consider $Z = M \Delta M_i$ (we take the symmetric difference of $M$ and $M_i$ as sets of edges). Since $M$ and $M_i$ do not necessarily match the same items then the edges in $Z$ induce a collection of alternating paths and cycles where each path $L$ has an item matched by $M$ and not by $M_i$ at one end, and an item matched by $M_i$ and not by $M$ at the other hand. Except for its two ends, an alternating path contains items that are matched by both $M$ and $M_i$. From the optimality and the uniqueness of $M$ follows that for each path the value of $M$ is larger than the value of $M_i$.

Since $c$ is matched by $M$ and not by $M_i$ there is a path $L$ in $Z$ that starts at $c$ and ends at some item that is matched by $M_i$ and not by $M$.

It follows that all the items in $L$ are in $M_i$ and if we match them according to $M$ then the value that we gain from them increases. This contradicts the optimality of $M_i$.

(Note that, in fact, there are no cycles in $Z$, since they will imply that there are multiple optimal solutions, contradicting the uniqueness of $M_i$ and $M$.)

Lemma 18 implies that if we collect all items that are in the optimal solution of the subset of items that precedes them then the set of items that we have at the end contains the optimal solution. The next question is: how large is the subset of the items which we retain? The next lemma answers this question in an average sense.

Lemma 19. Assume that the first stage the algorithm receives the items in a random order. Then the expected number of items that the first stage keeps is $k + k \sum_{i=k+1}^{n} \frac{1}{i} = O(k \log \frac{n}{k})$.
Each \( t^j_i \) for \( j \in J_i \) satisfies \( \Pr_{c \sim D} [v(c) \geq t^j_i \text{ and } c \in P_i] = \frac{j}{dn} \).

Proof. Let \( X_i \) be an indicator that is one if and only if the \( i \)'th item belongs to \( M_i \). Condition the probability space on the set \( L_i \) of the first \( i \) items (but not on their order). Each element of \( L_i \) is equally likely to arrive last. So since \( |M_i| \leq k \), then the probability that the element arriving last in \( L_i \) is in \( \text{OPT}_i \) is at most \( \frac{k}{i} \) if \( k < i \) or at most 1 otherwise. It follows that \( \mathbb{E}[X_i | L_i] \leq \min\left\{ \frac{k}{i}, 1 \right\} \). Since this holds for any \( L_i \), it also holds unconditionally as well. The lemma now follows by linearity of expectation and the fact that \( \sum_{i=1}^n \frac{1}{i} \leq \log \frac{n}{k} \).

\section*{A.2 Generalization and concentration}

\textbf{Lemma (restatement of Lemma 16).} There exists a collection of \( N \) thresholds-policies such that \( |N| \leq k^{O(d)} \), and for every thresholds-policy \( T \in \mathcal{T} \) there are \( T^- \), \( T^+ \in \mathcal{N} \) such that

1. \( V^{T^-}(C) \leq V^T(C) \leq V^{T^+}(C) \) for every sample of items \( C \). (By taking expectations this also implies that \( \nu^{T^-} \leq \nu^T \leq \nu^{T^+} \).)

2. \( \nu^{T^+} - \nu^{T^-} \leq 10 \).

Proof. For every \( i \leq d \) and \( j \leq dn \) define thresholds \( t^j_i \in [0, 1] \) where \( t^0_i = 1 \) and for \( j > 0 \) set \( t^j_i \) to satisfy \( \Pr_{c \sim D} [v(c) \geq t^j_i \text{ and } c \in P_i] = \frac{j}{dn} \).

Note that \( t^0_i > t^1_i > \ldots \) (see Figure 1). Set

\[ J_i = \left\{ j : 0 \leq \frac{j}{dn} \leq \Pr_{c \sim D} [c \in P_i], j \in \mathbb{N} \right\}, \]

and define

\[ N_i = \{ t^j_i \mid j \in J_i \cap \{0, 1, \ldots, 10dk\} \} \cup \{0\} \]

\[ \mathcal{N} = N_1 \times N_2 \ldots \times N_d. \]

Note that indeed \( |\mathcal{N}| \leq (10dk + 2)^{d+1} = k^{O(d)} \).

We next show that \( \mathcal{N} \) satisfies items 1 and 2 in the statement of the lemma. Let \( T \in \mathcal{T} \) be an arbitrary thresholds-policy. The policies \( T^- = (t^-_i)_{i \leq d} \) and \( T^+ = (t^+_i)_{i \leq d} \) are derived by rounding \( t \) in each coordinate up and down respectively, to the closest policies in \( \mathcal{N} \) (so, the thresholds in \( T^+ \) are smaller than in \( T^- \); the “+” sign reflects that it retains more items and achieves a higher value). Formally, \( t^+_i = \max\{t \in \mathcal{N}_i : t \leq \}

\[ \frac{j}{dn} \] such \( t^j_i \)'s exist due to our assumption that \( D \) is atomless (see Section 3).
\[ t_i \} \text{ and } t_i^- = \min\{t \in N_i : t \geq t_i \} \] where \( t_i \) is the threshold for property \( i \) in \( T \). Therefore, for every sample \( C \sim D^n \), the set of items in \( C \) that are retained by \( T \) contains the set retained by \( T^- \) and is contained in the set retained by \( T^+ \). This implies item 1.

To derive item 2, observe that for every sample \( C \sim D^n \), the set of items in \( C \) that are retained by \( T^+ \) contains the set retained by \( T^- \) and is contained in the set retained by \( T^+ \). This implies item 1.

\[ V^{T^+}(C) - V^{T^-}(C) \leq |Z|, \] where \( Z \subseteq C \) denotes the set of items which participate in some canonical optimal solution for \( T^+ \) that are not retained by \( T^- \). Thus, it suffices to show that \( \mathbb{E}[|Z|] \leq 10 \). To this end put \( p_i = \Pr_{c \sim D}[v(c) \geq t_i \text{ and } c \in P_i] \) and partition \( Z \) into two disjoint sets \( Z = E \cup F \), where \( E \) is the set of all items \( c_j \in Z \) that are assigned by the optimal solution of \( T^+ \) to a property \( P_i \) where \( p_i < \frac{10k}{n} \), and \( F = Z \setminus E \). We claim that

- \( \mathbb{E}[|E|] \leq 1 \): for each \( P_i \) such that \( p_i < \frac{10k}{n} \) let \( G_i \subseteq P_i \) denote the set of items whose value \( v \in [t_i^+, t_i^-] \) (i.e. retained by \( T^+ \) and not by \( T^- \)). Note that \( E \subseteq \bigcup_i G_i \), and that \( \Pr_{c \sim D}[c \in G_i] \leq \frac{1}{dn} \). Thus, it follows that

\[
\mathbb{E}_{c \sim D^n}[|E|] \leq \mathbb{E}_{c \sim D^n}[|\bigcup_i G_i|] \leq \sum_i \mathbb{E}_{c \sim D^n}[|G_i|] \leq d \cdot \frac{n}{dn} \leq 1.
\]

- \( \mathbb{E}[|F|] \leq 9 \): note that \( \mathbb{E}[|F|] \leq k \cdot \Pr[|F| > 0] \) (because \( F \subseteq Z \) and \( |Z| \leq k \)). Thus, it suffices to show that \( \Pr[|F| > 0] \leq \frac{9}{k} \). Indeed, \( F \neq \emptyset \) only if there is a property \( P_i \) with \( p_i \geq \frac{10k}{n} \) such that less than \( k \) items from \( P_i \) are retained by \( T^- \). Fix a property \( P_i \) such that \( p_i \geq \frac{10k}{n} \) and let \( p_i^- = \Pr_{c \sim D}[v(c) \geq t_i^- \text{ and } c \in P_i] \). Since \( p_i^- \geq \frac{10k}{n} \), a multiplicative Chernoff bound yields that

\[
\Pr_{c \sim D^n}[\text{less than } k \text{ items from } P_i \text{ are retained by } T^-] \leq \exp\left(-\frac{(9/10)^2 \cdot 10k}{2 \cdot k^2}\right) \leq \frac{9}{k} \leq \frac{9}{d}. \]

Thus, it follows that \( v^{T^+} - v^{T^-} \leq 1 + k \cdot \frac{9}{k} = 10 \), which finishes the proof.
