ABSTRACT

Self-supervised pre-training of a speech foundation model, followed by supervised fine-tuning, has shown impressive quality improvements on automatic speech recognition (ASR) tasks. Fine-tuning separate foundation models for many downstream tasks are expensive since the foundation model is usually very big. Parameter-efficient fine-tuning methods (e.g., adapter, sparse update methods) offer an alternative paradigm where a small set of parameters are updated to adapt the foundation model to new tasks. However, these methods still suffer from a high computational memory cost and slow training speed because they require backpropagation through the entire neural network at each step. In the paper, we analyze the performance of features at different layers of a foundation model on the speech recognition task and propose a novel hierarchical feature fusion method for resource-efficient transfer learning from speech foundation models. Experimental results show that the proposed method can achieve better performance on speech recognition task than existing algorithms with fewer number of trainable parameters, less computational memory cost and faster training speed. After combining with Adapters at all layers, the proposed method can achieve the same performance as fine-tuning the whole model with 97% fewer trainable encoder parameters and 53% faster training speed.

Index Terms— speech recognition, foundation model, transfer learning

1. INTRODUCTION

A foundation model [1] is usually a big model trained on broad data (generally using self-supervision at scale) that can be fine-tuned to a wide range of downstream tasks and has aroused extensive attention due to its impressive quality improvements and emergent capabilities [2, 3, 4, 5]. In speech community, self-supervised pre-training speech foundation models on a large amount of unsupervised speech has shown impressive quality improvements on various speech recognition tasks [6, 7]. There are two main categories of speech self-supervised learning algorithms. One direction is to reconstruct (APC [8], MPC [9]) or predict (Wav2vec [10, 11, 12]) the input feature directly. The other direction is building a BERT-style self-supervised learning model by bridging the gap between continuous speech signal and discrete text tokens, such as Wav2vec 2.0 [13], HuBERT [14], w2v-BERT [15] and BEST-RQ [16]. After pre-training the speech foundation model using the self-supervised loss, we initialize the encoder of the downstream task using the pre-trained model and fine-tune it on the supervised data.

A large general-purpose foundation model with millions or even billions of parameters can be adapted to many downstream tasks. However, it is challenging to perform separate adaptations for many tasks efficiently with only a small amount of supervised data each task. There have been existing works investigating to reduce the number of parameters required for fine-tuning the foundation model. BitFit [17] proposes a sparse-finetuning method where only the bias terms of the foundation model are updated. Houlby et al. [18] propose to insert Adapter modules between the layers in the fixed pre-trained model and each module is a small trainable feed-forward neural network. Other works [19, 20] reduce the number of parameters further by exploiting a low-rank approximation of the Adapter. Although these parameter-efficient methods achieve decent performance on the downstream task with a significant reduction in the trainable parameters, their required computational memory cost and training time are still very high because of the following two reasons: 1) using the output of the highest layer in the foundation model only for downstream tasks, which leads to the inefficiency of the feature usage and requires to update the foundation model to adapt it to the downstream tasks; 2) adding/updating sparse parameters in the foundation model, which requires a full backpropagation process from the top to the bottom of the network to compute the gradients of the trainable parameters. Thus, a resource-efficient transfer learning method, which can achieve comparable performance with small number of trainable parameters, low computational memory cost and fast training speed, is required for efficient adaptation of the foundation model to many downstream tasks.

Recently, Pasad et al. [21] analyze the layer-wise features of a self-supervised (wav2vec2.0) pre-trained speech representation model and finds that the middle layers encode the most contextual and high-level information. The bottom or top few layers, on the other hand, focus on the lower-level information and encode more local representations. Arunkumar et al. [22] investigate the ensemble features of self-supervised pre-trained models for ASR and finds that features from different self-supervised learning methods are complementary and the ensemble of features is beneficial for the downstream speech recognition tasks. Although behaviors of the layer-wise features and features from multiple self-supervised pre-trained models are explored, neither of them consider the resource efficiency in the fine-tuning stage and there is no investigation about the feature fusion of layer-wise features from a single pre-trained model on downstream tasks.

In this paper, we propose a novel resource-efficient transfer learning method for speech foundation models. Specifically, we treat the foundation model as a frozen feature extractor and fuse the multi-level features from the foundation model hierarchically. We conduct extensive experiments to investigate different ways of feature fusion for the foundation model. Experimental results show that the proposed method can achieve better performance on the ASR task than existing parameter-efficient fine-tuning algorithms with fewer number of trainable parameters, less computational memory cost and faster training speed. After combining with Adapters at
all layers, the proposed method can achieve the same performance as fine-tuning the whole model with 97% fewer trainable encoder parameters and 53% faster training speed.

2. EXPERIMENTAL SETUP

2.1. Foundation Model And Task

The foundation model used in the paper is a 2-layer convolutional network followed by a 24-layer conformer encoder with hidden dimension 1024 and about 600M parameters in total. Each conformer layer [23] is a convolution-augmented transformer network, which consists of attention, feed-forward and convolutional modules. The model input is a vector of size 128 logMel features and SpecAugment [24] is also applied to increase model robustness. We pre-train the 600M conformer encoder using the BEST-RQ [16] algorithm for 800K steps. For the downstream speech recognition task, we initialize the encoder using the pre-trained speech foundation model and the output of the encoder is used as input to an RNN-T [6] along with a 6-layer LSTM decoder and dimension 768. We train with Adam optimizer for both pre-training and fine-tuning, and use exponential moving averaging (EMA) with decay rate 0.9999 for fine-tuning only. We update the trainable encoder parameters and LSTM decoder which has 124M trainable parameters on Voice Search data for 100K steps. If not described explicitly, the parameter efficiency refers to the reduction of the trainable parameters in the encoder only. All experiments are performed on TPUs.

2.2. Training Data

We use two sources of training data in this work. Following [6], we collect 800K hours unsupervised English Youtube data and pre-train the 600M foundation model on the randomly segmented audio-only Youtube speech using the BEST-RQ algorithm [16]. In addition, the supervised English Voice Search (VS) data contains 5K hours of labeled voice search audio [25] and is used to fine-tune the conformer encoder and RNNT-T decoder for the ASR task. All data are collected and deidentified in accordance with Google AI principles [26].

2.3. Evaluation

In this paper, we calculate the word error rate (WER) on the Voice Search (VS) test dataset to measure the quality of the model on the downstream speech recognition task. Apart from WER, we compare the number of trainable parameters, computational memory cost and training speed at the same time for resource efficiency. The target of this paper is to propose a method, which can achieve low WER with small number of trainable parameters, low computational memory cost and fast training speed.

3. LINEAR FEATURE FUSION OF THE FOUNDATION MODEL

Previous parameter-efficient fine-tuning methods update the sparse parameters in the foundation model and use the output of the highest encoder layer only as the input to the RNN-T decoder, while the outputs of the intermediate layers are dropped after the forward pass. The proposed feature fusion method treat the foundation model as a frozen feature extractor and fuse the multi-level features from different layers linearly or hierarchically. Because there is no need to perform backward pass in the foundation model and only a few parameters are added on top of the outputs of the intermediate layers, the proposed feature fusion method is parameter-efficient and computation-efficient.

3.1. Performance of Single Layer Features

To study the performance of the features from different layers of the foundation model, we extract outputs from layers \{1, 3, 5, 10, 12, 14, 19, 21, 23\} respectively and update the 124M 6-layer LSTM decoder only on the Voice Search data. Figure 1 shows the WER of the corresponding layers and results present that models using features from middle layers perform better on the speech recognition task than features from bottom or top layers. This observation is consistent with [21] that middle layers encode more contextual and high-level information which is more helpful for the speech recognition task than bottom or top layers.

3.2. Linear Feature Fusion From Multiple Layers

From Section 3.1, we know that features from different layers show different performance on the downstream speech recognition task. To investigate whether these features are complementary, we propose a linear feature fusion method and combine features from different layers linearly. As in Figure 2, we firstly concatenate the features from multiple layers and project the concatenated feature to the
required dimension using a fully-connected neural network. The decoder receives the output of the projector as input. All the conformer layers in the encoder are fixed while we update feature projector and decoder only using the RNN-T loss.

Table 1: Fusing features from multiple layers of the foundation model. Feature projector is a 1-layer fully-connected network for all combinations.

| Layer index | # Parameters In Feature Projector | VS WER (%) |
|-------------|----------------------------------|------------|
| 11          | 0.6 M                            | 11.2       |
| 23          | 0.6 M                            | 91.9       |
| 11, 23      | 1.3 M                            | 10.8       |
| 5, 11, 17, 23 | 2.6 M                      | 9.3        |
| 2, 5, 8, 11, 14, 17, 20, 23 | 5.2 M                  | 8.1        |
| 1, 3, 5, 7, 9, 11, 13, 15, 17, 19, 21, 23 | 7.9 M | 8.0 |

Fig. 4: $\ell_2$ norm of the learned weight of each layer when fusing features from 12 layers.

3.3. Increasing Depth of The Feature Projector

We also explore to learn non-linear feature fusion by increasing the depth of the feature projector in Figure 2. In Table 2, we increase the depth of the fully-connected network from 1 to 4 layers with ReLU activation while extracting features from the same 12 layers used in the previous experiments, which was found to give the best results. Experimental results show that the model gets a better WER with a deeper feature projector and the VS WER becomes saturated at about 7.4% after adding up to 3 fully-connected layers.

Table 2: Increasing depth of the feature projector. Fusing features from 12 layers as it gives the best results.

| # Layers | # Parameters In Feature Projector | VS WER (%) |
|----------|----------------------------------|------------|
| 1        | 7.9 M                            | 8.0        |
| 2        | 8.3 M                            | 7.5        |
| 3        | 8.7 M                            | 7.4        |
| 4        | 9.1 M                            | 7.4        |

4. HIERARCHICAL FEATURE FUSION OF THE FOUNDATION MODEL

Knowing that features from different layers encode different levels of information, we also explore to fuse features in a hierarchical way rather than linearly. In this section, we propose a hierarchical feature fusion method and compare it with other parameter-efficient fine-tuning algorithms.

4.1. Hierarchical Feature Fusion From Multiple Layers

As in Figure 3, we compare two hierarchical feature fusion methods (balanced and unbalanced) for the speech foundation model. For the balanced feature fusion method (HFF-b), we project and concatenate the neighboring pair-wise features, treating all layers equally. For the unbalanced feature fusion method (HFF-ub), on the other hand, we project and concatenate the neighboring features from bottom to the middle and from top to the middle. The intuition is that the middle layers encode high-level information while the bottom or top layers...
encode low-level information, such that more encoding is required
for the features from these layers.

Table 4: Comparison between balanced and unbalanced hierarchi-
cal feature fusion methods. Fusing features from 12 layers.

| Methods                      | # Parameters in Feature Projector | VS WER |
|------------------------------|-----------------------------------|--------|
| HFF-b                        | 12.3 M                            | 7.0    |
| HFF-ub                       | 12.3 M                            | 7.2    |

We use a 1-layer fully-connected network as FP in Figure 3 and
the projector in the “Concat & Project” is a 3-layer fully-connected
network. The FP projects a 1024-d feature to 512-d, such that the
feature dimension remains unchanged after concatenation. Table 4
shows that both methods achieve better VS WER than linear feature
fusion, and HFF-b performs better than the HFF-ub on the speech
recognition task with the same amount of parameters in the feature
projector. Therefore, we use balanced hierarchical feature fusion
(HFF-b) in the following experiments.

4.2. Comparison with Parameter-Efficient Fine-Tuning Metho-
ds
To validate the proposed hierarchical feature fusion method, we
compare it to several related algorithms. Specifically, we compare
with two representative and strong parameter-efficient methods:
BitFit [27] and Adapter [18]. Each adapter module is inserted
after each conformer encoder layer and is a randomly initialized
2-layer feed-forward network with the bottleneck dimension d from
{128, 256, 512}. We also fine-tune the highest conformer en-
coder layer (FTHST) as a baseline, which is computation-efficient
because no backpropagation is required for the lower encoder lay-
ers. The parameter-efficient methods are applied to fine-tune the
600M conformer encoder only, and the whole randomly initialized
124M LSTM decoder is also updated simultaneously. Because
the LSTM decoders are the same for all compared methods, we
only compare the number of trainable encoder parameters in the
experiments regarding parameter efficiency. Although the best VS
WER can be achieved if we fine-tune all parameters of the model,
it costs too much computational memory 13567 MB and the train-
ing speed is very slow at 1270 examples/sec. Results in Table 3
show that Adapter’s performance is better than BitFit or FTHS,
but gets stuck at 6.1 VS WER even if increasing the bottleneck
dimension from 128 to 512. However, the Adapter(d=128) at all
layers’s training speed is 22% slower and computational memory
cost is 64% higher than FTHS. With a very similar computational
memory cost and training speed to FTHS, HFF-b can improve VS
WER from 15.8% to 7.0%. Comparing with Adapter(d=128) at
layers {13, 15, 17, 19, 21, 23}, HFF-b achieves better VS WER
with 12% faster training speed and 18% lower computational mem-
ory cost. Combining the HFF-b with Adapter(d=128) at layers
{13, 15, 17, 19, 21, 23}, we can achieve better VS WER 6.0% than
all compared parameter-efficient methods with fewer num-
ber of trainable parameters, less computational memory cost and
faster training speed. If combining the proposed HFF-b with
Adapter(d = 128) at all layers, we can achieve the same WER
as fine-tuning all parameters of the RNN-T model with 97% fewer
 trainable encoder parameters and 53% faster training speed.

5. CONCLUSION

In this paper, we analyze the behavior of features from different
layers of the foundation model for speech recognition task and
propose a hierarchical feature fusion method for resource-efficient
transfer learning from the speech foundation model. Extensive re-
results demonstrate that it achieves promising performance on the
speech recognition task with fewer trainable encoder parameters,
less computational cost and faster training speed.
