Abstract

Purpose: To identify the value of prostate-specific antigen density (PSAD) and prostate-specific antigen density of the transition zone (PSADTZ) in improving the sensitivity and specificity of the prostate multiparameter magnetic resonance imaging (mp-MRI), for the purpose of predicting prostate cancer (PCa) and grade reclassification in men with prostate-specific antigen (PSA) between 4 and 20 ng/mL to reduce unnecessary prostate biopsies.

Patients and Methods: Between 2018 and 2020, we retrospectively identified 283 consecutive men in Shanghai Jiao Tong University Affiliated Sixth People's Hospital who had mp-MRI and PSA test within 3 months before prostate biopsies. Total prostate volume (TPV) and transition zone volume (TZV) were measured on mp-MRI. PSA, PSAD, and PSADTZ were compared to improve the sensitivity and specificity of positive biopsy cores and pathological stage by univariate analyses and through the receiver operating curve (ROC). We were focused primarily on the MRI-positive patients with PSA levels of 4-20ng/ml who were most likely subjected to unnecessary repeated prostate biopsies.

Results: Of the 283 patients, 138 (48.8%) had PCa and in 145 (51.2%) a benign prostate disease was diagnosed. PSA, PSAD, and PSADTZ were significantly related to biopsy, and equally able to predict higher pathological stage. The receiver operating curve (AUC) for predicting the presence of PCa in all patients was 58.06 for PSA, 72.13 for PSAD and 78.28 for PSADTZ. In addition, the AUC for predicting higher pathological stage in PCa patients was 65.71 for PSA, 65.46 for PSAD and 69.81 for PSADTZ. For 228 MRI-positive patients, the AUC for predicting the presence of PCa was 61.31 for PSA, 74.00 for PSAD and 80.13 for PSADTZ. No difference among the PSA, PSAD, and PSADTZ was found in 55 MRI-negative patients. Conclusion: The determination of PSADTZ had higher diagnostic accuracy for PCa than that based on PSA or PSAD. For MRI-positive patients, PSADTZ promote a more effective and simple method for PCa detection, and may be useful for decreasing the burden of surveillance prostate biopsies.

Background

Prostate cancer (PCa) is the second most prevalent malignancy and the fifth reason for mortality caused by cancer in men around the world [1, 2]. Although the incidence of PCa in Asia is lower than that in Northern America, Oceania, and Northern Europe, it has been increasing rapidly. In the recent 5 years, with the wide application of serum prostate-specific antigen (PSA) examination, China has an increasing trend in the incidence of PCa (2.6%/yr)[1]. PSA, multiparameter MRI (mp-MRI), and transrectal prostate ultrasound (TRUS) all play essential roles in PCa screening and in the selection of appropriate candidate for biopsy[3]. For the prostate biopsy is invasive[4] and costly[5], it’s necessary for doctors to make accurate judgment. PSA screening has been mostly used for early PCa detection. When the PSA level is higher than 20 ng/ml, the serum PSA test got significantly higher accurate (largest to 87.2%[6]) in predicting PCa[7, 8]. However, serum PSA is not disease specific. Not only prostate cancer can cause the increase of PSA, Benign prostate diseases, such as benign prostatic hyperplasia and prostatitis may also cause PSA elevation. In prostatic hyperplasia, the number of prostate cells and the prostate volume
increases, resulting in increased secretion of PSA, thereby increase the serum PSA[9]. According to the literatures, however, the false-positive rate was up to 69.93% in patients with PSA levels of 4–20 ng/mL[10, 11]. As two most commonly imaging examinations, TRUS and mp-MRI can partly improve the positive diagnostic rate of PCa, but also go with insufficient sensitivity and specificity, especially when the PSA ranges from 4–20ng/mL[8, 12]. New biomarkers, such as Prostate-specific antigen isoform 2 (p2PSA) and Prostate Health Index (PHI) have not yet universal[13]. Therefore, MRI-positive patients with PSA levels of 4-20ng/mL are most likely subjected to unnecessary repeated prostate biopsies.

The increase of PSA caused by prostatic hyperplasia is related to the increase of prostate volume. The increase of PSA caused by prostate cancer is less related to the volume of prostate. Therefore, the serum PSA per prostate volume of prostate cancer may be higher than that of normal or BPH people. Some studies found that the use of PSAD in the diagnosis of prostate cancer which has a positive significance. And other studies have further found that the effect of PSA density of the transition zone (PSADTZ) on prostate cancer and prostatic hyperplasia was better than that of simply using PSAD for[14]. The purpose of this study was to compare the performance of PSAD, PSADTZ and PSA in the detection of PCa and risk stratification while particularly focusing on MRI-positive patients with PSA serum levels of 4∼20 ng/mL.

Patients And Methods

Study population

This retrospective study was approved by local ethics committee, and given the retrospective design, the requirement for written consent was waived. From January 2018 to June 2020, a total of 941 patients, who had a systematic biopsy at Shanghai Jiao Tong University Affiliated Sixth People's Hospital, were retrospectively investigated. Patients underwent TRUS-guided transperineal prostate biopsy, served as the reference standard[15]. We excluded men with (1) absence of clinical information within 3 months before biopsy (n=103); (2) PSA level <4ng/ml (n=63) or >20ng/ml (n=274); (3) absence of mp-MRI within 3 months before biopsy (n=197); (4) age <50 (n=1) or >84 (n=16); (5) a history of treatments for benign prostate hyperplasia or PCa (n=4); (6) PSA elevation with urinary tract infection.

Clinical and pathologic characteristics of patients, including age, PSA testing, and Gleason score, were obtained from pathology reports. The biopsy samples were analysed and reported on the basis of the International Society of Urological Pathology (ISUP) 2014 modified Gleason score grading system[16]. PI-RADS scores (version 2), prostate volume and transition zone volume were also obtained from MRI reports. The final study enrolled 283 patients, including 138 PCa patients and 145 patients without any histologic evidence of cancer. PSAD = total PSA (ng / mL) / prostate volume (cm³). The unit is ng / mL • cm⁻³. PSAT = total PSA (ng / mL) / prostate transition zone volume. The unit is ng / mL • cm⁻³.

MRI Examination and Images Analysis
All images were acquired with a 3-T MRI scanner (MAGNETOM Skyra, Siemens Healthcare), and a phased-array 18-channel body coil in combination with an integrated 32-channel spine coil was used for signal reception. The imaging protocol followed the standard of the European Society of Urology Radiology guidelines, and included T1-weighted Imaging (T1WI), T2-weighted Imaging (T2WI), diffusion-weighted imaging (DWI) with b values of 50, 1000, and 1500 s/mm² and dynamic contrast-enhanced imaging (DCE). Two dedicated radiologists blinded to both clinical and pathological information analyzed prostate mp-MRI images in consensus. According to the PI-RADSv2 criteria, all images and suspicious lesions were scored. When multiple suspicious lesions were detected, an index lesion considered as the one with the highest score was a representative PI-RADSv2 score of a patient in the study. PI-RADS score 1-2 is MRI negative, and PI-RADS score 3-5 is MRI positive.

TPV was calculated for each patient by using an open-source software (Sante DICOM Viewer Free, v4.0.14, https://www.santesoft.com/index.html). Two over five-year prostate MRI-experienced radiologists independently measured the anteroposterior, transverse and longitudinal maximum diameters of entire prostate and TPZ on T2WI images. Both readers were blinded to PSA levels and biopsy results. Subsequently, TPV and TZV were estimated through ellipsoid formulas: (maximum anteroposterior dimension) × (maximum transverse dimension) [both placed on the axial T2-WI] × (maximum longitudinal dimension) [placed on the sagittal T2-WI] ×0.52 [17].

Statistical analyses

GraphPad Prism software (ver. 8.0.2, Inc., CA, USA) was used for analysis, and Shapiro-Wilk test was used to assess the normal distribution of continuous variables. An unpaired t test was used to assess normally distributed continuous variables. The Mann–Whitney U test was used to assess non-normally distributed continuous variables. The ROC (Receiver Operating Characteristics) curve was employed to graphically demonstrate the sensitivities and specificities of the different diagnostic tests. The areas below the ROC curve (global accuracy) were also calculated and compared in pairs, through Medcalc software (ver. 19.7, Mariakerke, Belgium) as described by Delong [18]. Medcalc was also used to demonstrate the best cut-off point for each diagnosis test (PSA, PSAD and PSADTZ) as well as to calculate its respective positive predictive values (PPV), negative predictive values (NPV), sensitivities and specificities to predict PCa. All statistical analysis was performed considering p < 0.05 statistically significant and with a 95% trust interval.

Results

Patient characteristics.

In this study, 941 men underwent prostate biopsy, among whom 283 patients were included in the final analysis. Based on the results of the initial biopsy, 138 patients were PCa-positive and 145 were PCa-negative, resulting in a detection rate of 48.8%. Demographic and clinical characteristics, as well as MRI findings of the entire study cohort, are summarized in Table 1. The median time between mp-MRI and the histopathological examination was 22 days (range 3-90 days). The analyzed parameters except age did
not follow normal distribution and thus, are summarized with median and IQR. The mean age was 70 years (range 51-84 years). The median PSA level, median TPV, median TZV, median TZV/TPV, median PSAD, and median PSADTZ of 283 patients were 10.00ng/ml (IQR 7.00-13.59ng/mL), 56.84ml (IQR 41.61-80.21mL), 26.27mL (IQR 15.37-45.59mL), 0.47 (IQR 0.37-0.56), 0.17ng/mL/mL(IQR 0.11-0.25ng/mL/mL) and 0.36 ng/mL/mL (IQR 0.21-0.62ng/mL/mL). Patients with PCa in ISUP grade 1-5 were 30 (21.7%), 36 (26.1%), 41 (29.7%), 13 (9.4%) and 18 (13.0%) respectively.
Table 1
The characteristics of MRI-positive patients and MRI-negative patients, and comparison of PCa patients and non-PCa patients.

| Characteristic                        | Overall     | Patients without PCa | Patients with PCa | P    |
|---------------------------------------|-------------|----------------------|-------------------|------|

**Diagnostic performance of clinical characteristics and mp-MRI in the detection of prostate cancer**

As shown in Table 1, there were no significant differences in the mean patient age between PCa group and non-PCa group (*P* = 0.1628). The PSA level (11.19 vs 9.08, *P*=0.0192), PSAD (0.21 vs 0.13, *P*<0.0001) and PSADTZ (0.53 vs 0.25, *P*<0.0001) were significantly higher in the PCa group than in the non-PCa group, but the TPV (49.31 vs 69.44, *P*<0.0001), TZV (17.82 vs 36.06, *P*<0.0001) and TZV/TPV (0.40 vs 0.53, *P*<0.0001) was significantly lower in the PCa group than in the non-PCa group. To examine the diagnostic efficacy of PSA, PSAD and PSADTZ, ROC curves of these three classifiers for predicting PCa were drawn (Figure 1). The AUC values of PSA, PSAD and PSADTZ were 0.5806, 0.7213 and 0.7828, and every two of three parameters showed significant differences (*P*<0.0001), which means PSADTZ is a better index for predicting PCa when the PSA levels of patients are 4~20 ng/ml.

Among the 138 patients with confirmed PCa, 120 were positive on mp-MRI and 18 were negative. Of the 145 patients with benign diagnoses, 108 were positive on mp-MRI and 37 were negative. The patient-based sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and likelihood ratio of mp-MRI were 86.96% (95% CI 80.32-91.59%), 25.52% (95% CI 19.12-33.18%), 52.63% (95% CI 46.16-59.02), 67.27% (95% CI 54.10-78.19%) and 1.167 respectively (Table 2).

**Comparing the efficiency of PSA, PSAD and PSADTZ in the detection of risk stratification.**

Based on the differences of prognosis, 138 PCa patients were divided into lower-risk group (Gleason score ≤ 6) and higher-risk group (Gleason score ≥ 7). Table 3 showed the clinical parameters of two groups. As we can see, the age and PV of two groups made no difference. Higher-risk group got lower TZV (15.89 vs 23.44, *P*=0.0195 and TZV/TPV (0.39 vs 0.43, *P*=0.03681), but the PSA level (11.56 vs 8.70, *P*=0.0082), PSAD (0.23 vs 0.16, *P*=0.0093) and PSADTZ (0.63 vs 0.37, *P*=0.0008) of them were much lower than the lower-risk group.
higher. ROC curves of PSA, PSAD and PSADTZ for predicting prognosis of PCa patients and the comparison between these three parameters were shown in Figure 2. The AUC value of PSA, PSAD and PSADTZ were 0.6571, 0.6546 and 0.6981 respectively, however, there was no significant difference among them.

| Characteristic          | Gleason score ≤ 6 | Gleason score ≥ 7 | P    |
|-------------------------|-------------------|-------------------|------|
| N                       | 30                | 108               |      |
| Median age (IQR), years | 71 (65-76)        | 71 (66-74)        | 0.6835|
| Median PSA level (IQR), ng/ml | 8.70 (6.94-11.87) | 11.56 (7.98-14.45) | 0.0082 |
| Median TPV (IQR), ml    | 52.92 (40.56-69.83) | 48.27 (32.06-58.80) | 0.1557 |
| Median TZV (IQR), ml    | 23.44 (16.33-31.72) | 15.89 (11.71-28.67) | 0.0195 |
| Median TZV/TPV (IQR)    | 0.43 (0.36-0.50)  | 0.39 (0.31-0.48)  | 0.0368 |
| Median PSAD (IQR), ng/ml/ml | 0.16 (0.10-0.24) | 0.23 (0.15-0.34) | 0.0093 |
| Median PSADTZ (IQR), ng/ml/ml | 0.37 (0.23-0.61) | 0.63 (0.34-0.98) | 0.0008 |

Comparison of PSA, PSAD and PSADTZ between non-PCa group and PCa group when the mp-MRI exam is positive.

For the specificity of mp-MRI in our study was only 25.52%, we divided patients into MRI-positive group and MRI-negative group to make further comparison. Demographic and clinical characteristics of MRI-positive patients were shown in Table 1. There were no significant differences in the mean patient age between PCa group and non-PCa group (P = 0.0793). The PSA level (11.13 vs 8.61, P = 0.0032), PSAD (0.23 vs 0.13, P < 0.0001) and PSADTZ (0.61 vs 0.25, P < 0.0001) were significantly higher in the PCa group than in the non-PCa group, but the TPV (48.27 vs 66.98, P < 0.0001), TZV (16.77 vs 34.81, P < 0.0001) and TZV/TPV (0.39 vs 0.53, P < 0.0001) was significantly lower in the PCa group than in the non-PCa group. ROC curves of PSA, PSAD and PSADTZ for predicting PCa in MRI-positive patients were shown in Figure 3, and the comparison between these three parameters was shown in Table 4. The AUC value of PSADTZ (0.8013) was higher than PSA (0.6131) and PSAD (0.7400). When we chose the best cut-off values of PSA, PSAD, PSADTZ (11.24, 0.2277 and 0.3844, respectively) for predicting PCa, the sensitivities were 50.00%, 52.50% and 70.83%, respectively and the specificities were 72.22%, 87.96% and 74.07%, respectively.
Table 4
The difference comparison between AUCs of PSA, PSAD and PSADTZ for predicting PCa in MRI-positive patients, and the cut-off points that have produced the best sensibility and specificity rates.

| Characteristic | AUC (95% CI)       | Z statistic | P      | Cut-off point | Sensitivity | Specificity |
|---------------|--------------------|-------------|--------|---------------|-------------|-------------|
| PSA           | 0.6131 (0.5397 - 0.6865) | 0.0032      |        | 11.24         | 0.5000      | 0.7222      |
| PSAD          | 0.7400 (0.6765 - 0.8034) | <0.0001     | 0.2277 | 0.5250        | 0.8796      |
| PSADTZ        | 0.8013 (0.7452 - 0.8574) | <0.0001     | 0.3844 | 0.7083        | 0.7407      |
| PSA ~ PSAD    | /                  | 3.808       | 0.0001 |               |             |             |
| PSA ~ PSADTZ | /                  | 4.918       | <0.0001|               |             |             |
| PSAD ~ PSADTZ | /                 | 4.029       | <0.0001|               |             |             |

Comparison of PSA, PSAD and PSADTZ between non-PCa group and PCa group when the mp-MRI exam is negative.

As shown in the bottom of Table 1, the TPV (61.98 vs 79.00, P=0.258) and TZV (30.29 vs 46.00, P=0.212) were lower in the PCa group than in the non-PCa group, but there were no significant differences in age (P=0.3041), PSA (P=0.5907), TZV/TPV (P=0.0786), PSAD (P=0.0803) and PSADTZ (P=0.0630) between PCa group and non-PCa group. As matter of fact that few MRI-negative patients accepted prostate biopsy, no further comparison was made.

Discussion

PCa is one of the most common malignant tumors in the urological system, and it is the sixth leading cause of cancer death (7.4% of deaths) among men worldwide[19]. It is usually suspected in cases of increased serum PSA levels and/or abnormal digital rectal examination (DRE). In these patients, the standard method to diagnose PCa is prostate biopsy. But any prostate biopsy is associated with a risk of infection (1–8%) and an increased risk of life-threatening sepsis (1–4%), as a consequence of increasing antibiotic resistance[20, 21]. Other associated morbidities include dysuria, hematospermia, haematuria, rectal bleeding, vasovagal episodes and urinary retention[21, 22]. These drawbacks of prostate biopsy limit the willingness of physicians and patients to perform and undergo potentially unnecessary biopsies. The estimated false-negative rate of systematic biopsy for any cancer is 25–40% [23].

PSA was considered as tumor marker of PCa, but BPH may also cause PSA elevation. In view of this, Benson et al[24] think that PSA combined with prostate volume can be more accurate to evaluate prostate cancer risk than PSA alone. That is PSA density (PSAD), which is the ratio of serum total PSA to
total prostate volume. Studies have shown that PSAD can increase the sensitivity of serum PSA in the
diagnosis of prostate cancer, especially when serum PSA is low[Sci Rep. 2020 Mar 20;10(1):5157].
Lodeta et al[25] analysis 125 cases of PSA patients at the 4-10ng/ml level, the results showed that PSA
was not statistically significant between non-PCa and PCa groups, but differences of PSAD was
significant between the two groups(P=0.002), and with PSAD≥0.15ng/ml/ml as cutoff point, the
sensitivity is 86.7%. BPH mainly occurs in the transitional zone, while prostate cancer mostly occurs in
the peripheral zone. The PSA level enhancement is mainly related to the size of the transitional zone.
Therefore, someone proposed PSADTZ should be used to identify BPH and PCa. Kalish et al[26] analyze
21 cases PCa and 38 cases BPH in PSA range 4-10ng/ml, found that PSADTZ had statistical significance
between the two groups, while PSA and PSAD between the two groups was not statistically significant.
They get conclusion that PSADTZ is more accurate to distinguish the prostate cancer than the PSA and
PSAD. Kikuchi et al[27] got the similar conclusion and found that PSADTZ has the largest AUC in the PSA
gray area, which can avoid unnecessary prostate biopsy (68/117). Tang et al[28] found that PSADTZ can
increase the detection rate of prostate cancer in the Chinese population of PSA 4-10ng/ml and 10.1-
20ng/ml. Our current results found that the AUC values of PSA, PSAD and PSADTZ were 0.5806, 0.7213
and 0.7828, and every two of three parameters showed significant differences (P<0.0001), indicating that
PSADTZ was a better index for predicting PCa when the PSA levels of patients were 4~20
ng/mL. Additionally, we discovered that the AUC value of PSA, PSAD and PSADTZ were no significant
difference between the lower-risk and higher-risk Pca groups, which may be attributed to the fewer
samples and need to be explored in the future study.

Multiparametric prostate MRI (mp-MRI) is the combination of anatomic (traditional) MRI with functional
MRI techniques and is useful imaging modality for interrogating the prostate gland. It is an emerging
imaging modality for diagnosis, characterization, staging, and treatment planning of PCa. The technique,
results reporting, and its role in clinical practice have been the subject of significant development over the
last decade. Even so, mp-MRI still has false positive and false negative results. Therefore, our main
purpose is to reduce unnecessary biopsy by combining serum PSA with mp-MRI measurement
parameters. The Prostate Imaging Reporting and Data System version 1(PI-RADS v1) was created to
address the need for a universal system when performing, interpreting, and reporting prostate mpMRI for
tumor identification, risk stratification, and to guide image-guided biopsy in 2012. It changes the
diagnosis of MRI from a descriptive to an objective diagnosis. PI-RADS v2 was developed in 2015 in order
to address the aforementioned limitations of PI-RADS v1. The aims of PI-RADS v2 were to optimize
interdisciplinary communication and decrease variability in describe. Increased serum PSA levels and PI-
RADS score≥3 are indications of prostate biopsy, but there are still negative results in these patients. In
this study, the proportion reached 47.4%. Therefore, it is needful to reduce unnecessary biopsy. According
to MRI imaging of prostate zonal anatomy, the prostate comprises a peripheral zone (PZ), a transition
zone (TZ), a central zone, and an anterior fibromuscular stroma[29]. The density parameters, such as
PSAD and PSADTZ, are ratios obtained by dividing PSA level by total prostate and transition zone
volume. Both parameters have been introduced to improve the diagnostic accuracy in prostate cancer
detection and predict prostate cancer stage[6, 30], however, the suggested cut-off data is still highly
debated[31] and no study have reported these parameters on both MRI-negative and MRI-positive Pca patients[30]. In our study, the mean differences in PSA, PSAD, PSADTZ between the non-PCa group and the PCa group in the MRI-positive patients have statistic significance. The determination of PSADTZ had higher diagnostic accuracy for PCa than that based on PSA or PSAD. Therefore, PSADTZ promote a more effective and simple method for PCa detection, and may be useful for decreasing the burden of surveillance prostate biopsies for MRI-positive patients.

The present study had some limitations. It was a retrospective, single-center study and the sample size of our study was small especially in patients with negative MRI. Multicenter studies will be carried out to further validate these results. Despite these limitations, the findings of this study may impact current clinical practice.

Conclusion

The determination of PSADTZ had higher diagnostic accuracy for PCa than that based on PSA or PSAD. For MRI-positive patients, PSADTZ promote a more effective and simple method for PCa detection, and may be useful for decreasing the burden of surveillance prostate biopsies, the AUC for predicting the presence of PCa was 61.31 for PSA, 74.00 for PSAD and 80.13 for PSADTZ.
