N-Butyl Cyanoacrylate Transvenous Arteriovenous Malformation Embolization with Arterial Balloon Assistance: Defining Parameters for a Transvenous Approach as a Potential Upfront Treatment Option in Managing Cerebral Arteriovenous Malformations

Abstract
Complete obliteration of arteriovenous malformations (AVMs) using a transvenous approach as the primary and stand-alone treatment modality has been increasingly considered as a useful endovascular approach in the treatment of AVMs. AVMs are typically treated with microsurgery, stereotactic radiosurgery, endovascular embolization, or some combination of the three methods. Preservation of the draining vein is a key requisite common to all treatment modalities. Transvenous embolization (TVE) is conventionally not recommended as a stand-alone treatment for the vast majority of AVMs and has been thought to be best indicated when traditional approaches are considered less safe and when specific evaluation criteria are met. We report a case of a 35-year-old asymptomatic male diagnosed with a small intracranial AVM adjacent to the right motor strip which was managed utilizing this approach. We employed endovascular embolization via a transvenous approach with arterial balloon assistance due to the small size of the nidus, eloquent location, en passage arterial supply proximal to the venous varix, and a single draining vein from the fistula. This case illustrates the selective indications and technical nuances of TVE approach in managing AVMs as a potential upfront treatment option. When patients harbor AVMs with specific angio-architectural findings as outlined, TVE utilizing Onyx or N-butyl cyanoacrylate can be safely performed as a primary treatment modality.

Keywords: Arteriovenous malformation, balloon assistance, transvenous embolization

Introduction
Arteriovenous malformations (AVMs) of the brain parenchyma are frequently encountered vascular anomalies with a myriad of clinical presentation. An inherent defect in the vascular smooth muscle layer predisposes them to hemorrhage which can be potentially fatal. These lesions can be managed by conventional microsurgical excision, stereotactic radiosurgery (SRS), endovascular embolization, or some combination of the three depending largely on their size and anatomic location, clinical presentation, and angio-architecture of the AVM. Obliteration of the arterial feeders with the preservation of venous drainage is the key factor common to all of these treatment modalities.

Endovascular approaches offer the neuro-interventionalists a minimally invasive approach that can be utilized as a part of SRS or presurgical strategy or as a potentially curative option. Transarterial embolization (TAE) approach is commonly employed to identify and obliterate the arterial feeders to the nidus and to penetrate the substance of the AVM. AVMs that lack a discrete arterial supply may not be amenable to endovascular treatment via a transarterial route. Such lesions can be considered for embolization through the venous side and embolized in a retrograde manner. A steep learning curve, technical challenges, and risk of complications have limited the utilization of this approach. However, Transvenous embolization (TVE) has a significant potential as an upfront treatment option in managing certain angio-architectural subtypes of AVMs effectively that theoretically could result in improved outcomes over current conventional treatment.

Case Report

Our patient was a 35-year-old asymptomatic male who was incidentally found to have a small (2 cm) intracranial AVM located in the right precentral cortical location on the dorsolateral aspect on a screening magnetic resonance imaging (MRI) of the head [Figure 1]. Magnetic resonance angiogram showed that the AVM was being supplied by distal M4 branches with the varix draining into the vein of Labbe through an intermediate vein and subsequently into the right transverse sinus [Figure 1]. No evidence of deep venous drainage was observed. Next, functional MRI was performed which determined the perilesional parenchyma to be eloquent [Figure 1]. Based on the size (2 cm) and eloquence, the patient was diagnosed with a Spetzler–Martin (SM) Grade II AVM.

A diagnostic angiogram was done which revealed a compact nidus with multiple en passage arterial feeders and a single draining venous varix [Figure 2]. It was determined that a safe embolization would be difficult to perform through a transarterial approach. Microsurgical excision and radiosurgery were considered as well. Given the high likelihood of at least a temporary if not permanent deficit with either SRS or microsurgery, we felt after reviewing the diagnostic portion of the study that the angioarchitecture was ideal for a TVE. The patient consented to the proposed procedure. A thorough understanding of the venous anatomy was required before moving forward with a venous approach considering the venous varix proximal to the drainage via vein of Labbe as well as the acute angulation of the vein of Labbe at its drainage into the transverse sinus [Figure 2].

Under general anesthesia, a short angiographic sheath (6F size) was introduced into the right common femoral artery using modified Seldinger’s technique. A Chaperon (MicroVention, Inc., CA) guide catheter with a vertebral inner catheter was then advanced up to the origin of the right common carotid artery and standard roadmap views (both anteroposterior and lateral) were obtained. Using roadmap guidance, a distal internal carotid artery (ICA) access catheter was further advanced coaxially with a Prowler 14 (DePuy Synthes Companies, MA) microcatheter in the distal middle cerebral artery. Selective distal middle cerebral arterial injection revealed the presence of en passage right middle cerebral branch supply to the AVM nidus with multiple small distal M4 branches with and a venous varix. Considering the lack of a clearly defined arterial feeder in our patient, a decision was made in favor of endovascular embolization via transvenous approach.

The left common femoral vein was accessed using a 5F short angiographic sheath. An Envoy 5F (DePuy Synthes Companies, MA) catheter was then initially navigated into the right transverse sinus over a 0.035 size Bentson microguidewire (Boston Scientific, MA). The vein of Labbe could not be accessed via the right transverse sinus directly due to the acute angulation at their junction [Figure 2]. We then removed the Envoy (DePuy Synthes Companies, MA) from the right transverse sinus and accessed the left transverse sinus. Given the new access distance from the left transverse sinus to the right vein of Labbe and into the proximal nidal drainage, a much longer catheter (180 cm) was required due to the alternate trajectory. Venous access was then secured using a non-Onyx-compatible Prowler 14 (DePuy Synthes Companies, MA) microcatheter (180 cm length) by navigating through the transverse sinuses from the left side to the right side and eventually to the venous varix via Labbe’s vein. Positioning of the venous catheter inside the varix was confirmed by microinjection. Little contrast was observed exiting the fistula, indicating that the catheter was occlusive. The arterial balloon (Scepter C 4 mm × 10 mm) (MicroVention Inc., CA) was then advanced through the Chaperon (MicroVention, Inc., CA) guide catheter in the right ICA to the arterial feeder and secured with roadmap assistance over a microwire. With the balloon inflated, contrast was injected into the varix from the venous side to confirm occlusion of the arterial flow.

With the Sceptre C (MicroVention Inc., CA) balloon inflated, 33% N-butyl cyanoacrylate (NBCA)/ethiodol mixture was then injected slowly through the Prowler 14 (DePuy Synthes Companies, MA) microcatheter into the venous varix. The varix expanded upon injection and trace...
amounts of NBCA were carried through the draining vein and the vein of Labbe prior to catheter extraction [Figure 3]. Following the catheter removal, the balloon was deflated and complete AVM occlusion on the arterial side was confirmed in an arterial angiogram. The procedure was completed uneventfully and the patient recovered well in the postoperative period without neurological deficit.

**Discussion**

Microsurgical excision, SRS, and endovascular embolization, typically through the arterial feeder, are common modalities of treatment in AVMs. Clinical presentation, size, location, and angio-anatomy of the nidus often dictate the treatment modality to be used.

Close proximity of the AVM to eloquent brain increases the risk for safe microsurgical resection.\(^6\) In patients with nidus volume of <3 cm\(^3\) treated with SRS, 1.9%–10% of patients experience hemorrhage and 2%–3% of cases develop irreversible neurological damage.\(^6\)–\(^8\) The risk may be even higher for patients with small AVMs in eloquent locations. If a clearly defined arterial feeder is identified angiographically, TAE can be safely presumed to be the most effective modality of treatment. When complex angioarchitecture of the nidus renders the AVM inaccessible via the arterial end, consideration of treatment utilizing a transvenous approach can be considered; however; arterial control as well as venous architecture plays a significant role in the safety profile of TVE.\(^3\)–\(^5\) Systemic or local hypotension is often helpful when embolizing an AVM through the venous side. Temporary arterial balloon placement as permitted by the arterial anatomy may further optimize the safety of nidus occlusion by this method. Primary risks associated with TVE include premature occlusion of the venous drainage or inadvertent arterial occlusion resulting in hemorrhage or ischemia.\(^9\) If carefully performed, TVE is an effective method to avoid potentially irreversible damage to eloquent tissue from radiation or edema from microsurgery. technique is growing and there exists a significant potential to its clinical applications.

Incidental diagnosis of an AVM in an eloquent location such as our patient has become a management dilemma, especially in the post-ARUBA trial era. However, with the advent of newer microcatheters and embolizing materials, neurosurgeons and neuro-interventionalists frequently consider endovascular treatment as a component of treatment. Where appropriate, TVE may increase the frequency of curative embolization when patients are carefully selected.

Experience with transvenous retrograde embolization of the AVMs has risen in the recent few years. Commonly agreed criteria for TVE include – small size (<3 cm), deeply seated nidus, lesions in eloquent location, lesions not amenable to microsurgical excision or SRS, ill-defined arterial feeders, inability to access the arterial supply, en passage arteries, and single venous drainage of the AVM.\[10-12\] Viana et al. were able to establish the application of TVE in superficial AVMs in their case series.\[11\] Table 1 summarizes the number of cases reported so far which utilized the TVE approach as an upfront option in managing AVMs.\[13-18\] Inability to access the arterial supply due to multiple small feeders in a deep-seated AVM was the leading rationale in all of these cases. Seven of 8 previous cases achieved complete occlusion of the nidus via an upfront TVE approach. Two patients developed complications in the form of inadvertent feeder branch occlusion and transient V1 hypoesthesia.

Our patient harbored an asymptomatic SM Grade II AVM in an eloquent region with significant risks associated with both SRS and microsurgery. The angio-anatomical complexity rendered a TAE high risk. We elected to treat the AVM utilizing a transvenous approach due to our ability to control the arterial side as well as due to its discrete single venous drainage outflow. We were able to demonstrate that an immediate complete occlusion of the nidus was achievable with the good outcome which further extends the utilization of TVE in such seemingly innocuous yet “deficit-prone” low-grade cortical AVMs.

It is interesting to note that none of the previous cases have utilized glue as embolizing material. In a previous study, authors have identified the usage of glue to be unsuitable in TVE approach due to the potential risk of immediate occlusion of draining vein.\[12\] However, we were successful in achieving complete occlusion of the nidus using glue without any complications. We considered NBCA as an appropriate choice because a longer microcatheter (180 cm) was required in our case as opposed to the usual length (150 cm) of Onyx-compatible microcatheter. Inadvertent early occlusion of draining vein and reflux was avoided by effectively occluding the draining vein using the diameter of the microcatheter, and flow arrest was established by inflating the balloon on the arterial side.

---

AVM – Arteriovenous malformation; SM – Spetzler-Martin; SAH – Subarachnoid hemorrhage; SCA – Superior cerebellar artery; ICV – Internal cerebral vein; VOG – Vein of Galen; ACA – Anterior cerebral artery; NBCA – N-butyl cyanoacrylate; TVE – Transvenous embolization; SS – Straight sinus; GK – Gamma knife
of the fistula. Thus, a good control of the injection was maintained with no significant outflow from the fistula into the draining vein. Arterial embolization using NBCA has shown complete occlusion rates typically between 5% and 15%, with earlier studies indicating a cure rate of up to 40%.\(^{19}\) Therefore, NBCA may still be considered in embolizing certain AVMs via this approach.

Arterial flow reduction is essential to safe TVE. Published studies initially utilized systemic hypotension; however, arterial balloon assistance when suitable is favored in our opinion. While performing TVE, induced hypotension by using a temporary arterial balloon placement is an effective strategy to eliminate or reduce arterial inflow into the nidus, thus improving venous side nidal embolic penetration and avoiding reflux of embolizing material while lowering the risk and controlling arterial side rupture.

**Conclusion**

When patients harbor AVMs with specific angio-architectural findings as outlined, TVE utilizing Onyx or NBCA can be safely performed as a primary treatment modality.
