Received 16 December 2020, Revised 15 June 2021, Accepted 9 July 2021

Abstract: *Background and aim — Gratiola officinalis* extract has antimicrobial properties, but its wound healing activity has not been described. *Material and Methods —* The aqueous solution of dry *Gratiola officinalis* extract was used for treatment of skin wounds with different routes of administration. In the experiment 40 white laboratory male rats with weight of 150±50 grams were subjected to the incised model of flat skin wounds in the interscapular region under the general anesthesia. A morphological study was carried out to assess the effectiveness of the therapy administered. *Results —* The most effective method of treatment was found to be local application of the extract, which reduced wound healing time by 8 days. Intramuscular and oral administrations reduce healing time by 6 days. Morphological signs of regeneration, which developed under the influence of *Gratiola officinalis* extract, allowed to estimate the wound healing activity. Clear differentiation and thickness of layers of the newly formed epidermis, a large number of thin-walled vessels and actively proliferating fibroblasts indicate an active regeneration process. *Conclusion —* This extract may be interesting to specialists in regenerative medicine as a remedy for treatment of wound processes.

Keywords: flavonoid-containing extract, wound-healing activity, *Gratiola officinalis*, experimental model, quercetin.

Introduction

Therapy of the wound process is a topical issue in modern medicine. According to the World Health organization (2017), 20% of the beds in surgical hospitals are the beds for patients with purulent diseases, and more than 40% of surgical patients are people with purulent inflammatory diseases and purulent wound complications [1]. Annually, about 5 million patients with purulent and inflammatory soft tissue diseases are registered in the Commonwealth of Independent States, which lead to fatal outcome in 7-11% of cases. These figures demonstrate the relevance of the problem of purulent infection in surgery. The key task is to find an effective and cost-effective drug with wound healing activity for the treatment of infected wounds [2].

The healing process is largely mediated by cytokines or growth factors, such as the tumor necrosis factor alpha (TNF-α), transformative growth factor beta (TGF-β), platelet growth factor (PDGF) and vascular endothelial growth factor (VEGF), which promote activation of a number of specialized cells and their migration to the wound site [3-5]. Polymorphonuclear neutrophil leukocytes and macrophages appear around wounds. Macrophages are the main phagocytic cells in the wound process, they provide an effective local antibacterial barrier [6, 7]. Macrophages can induce production of TNF-α, TGF-β, CD68 and other factors [8]. Proliferation of macrophages and epithelioid cells into fibroblasts and angiogenesis are triggered later. The processes of formation and maturation of connective tissue happen at the same time [9]. In this phase fibroblasts synthesize collagen and form new extracellular matrix [10]. Maturation includes the synthesis of extracellular matrix, tissue remodeling, wound contraction. A large number of cytokines and growth factors are involved in wound healing. Their functions are regulated, which reduces the time of wound healing and the risk of undesirable complications [11].

One of the promising areas of research in the treatment of wound processes is the study of wound healing activity of plant extracts. Most of plant extracts have complex chemical composition and therefore they are able to influence the activity of cytokines and growth factors [12]. A promising group of substances with antimicrobial and wound-healing properties are bioflavonoids, which are plant phenolic compounds [13].

In modern scientific literature, there is a direction of research, which are related to the study of wound healing activity of flavonoid-containing plant extracts. For example, the wound healing activity of aqueous extract of leaves and fractions of *Ficus exasperata* (Moraceae) and its assessment of safety on albino rats has been described [11]. The extract has antibacterial, anti-inflammatory, antioxidant, antipyretic effects, which together
have a direct impact on the wound healing rate [14]. Another example is the study of the effects and mechanisms of action of flavonoids of Blumea balsamifera (L.) DC. on the skin wound in rats. Authors have attempted to prove that the flavonoids of B. balsamifera can contribute to the increase of TGF-β expression in comparison with the control groups. They also emphasized that TGF-β plays a key role in attracting additional inflammatory cells, increasing tissue destruction of macrophages, and facilitating the formation of collagen and granulation tissue [15-17]. The increased expression of TGF-β in B. balsamifera groups may be caused by the stimulation of macrophages which is induced by flavonoids in wounds. As earlier studies have shown, macrophages may increase the TGF-β content [18].

One of the representatives of the flavonoid-containing extracts is the herbal extract from the Gratiola officinalis L. Different methods of extraction from Gratiola officinalis make it possible to obtain biologically active compositions with various pharmacological effects: laxative, vomiting, antispasmodic, diuretic, digitalis-like effect on the heart, antioxidant, antitumor and immunomodulatory, antipyretic, antimicrobial, anti-tuberculosis [19-21]. The flavonoid containing extract obtained by the authors’ method is not toxic and able to positively influence the state of red bone marrow [22, 23].

Aim of the study: to evaluate the wound healing effect of flavonoid containing Gratiola officinalis extract and to conduct a comparative analysis of wound healing in cases of topical, oral and intramuscular routes of its application.

Material and Methods
Extract preparation
The aqueous solution of the dry extract of Gratiola officinalis was used in the study. We used the material of Gratiola officinalis which was collected in Voskressevsky district of Saratov region in the vicinity of the Chardym village in July 2016. Dried leaves of Gratiola officinalis were pre-commminuted for more complete extraction.

The steamed extract of flowers and leaves of the Gratiola officinalis obtained by the patent method (Patent RU 2482863) was non-toxic due to its chemical composition, which had been previously confirmed in rats.

Extract, obtained by this method from the Gratiola officinalis, had the following chemical composition: 4-vinyl-2-methoxyphenol; 2,3-dihydro-3,5-dihydroxy-6-methyl-4H-pyran-4-one; 2,3-dihydrobenzofuran; 3-furancarboxylic acid; 5-hydroxyethyl-2-formaldehyde; ethyl-a-d-ribozide; 4-propyl phenol; pyrocatechin; L-luxose (pentosa); 6-deoxyhexose L-galactose; ethyl ester benzoylxic acid; hexadecanic acid (palmitic acid); homovanillic acid; glucose; 1,4-anhydro- d-mannitol; benzoic acid; quercetin.

The average value of quercetin in this extract according to the quercetin graduation reference standard (98%) Sigma, is 0.66%. Standardization of the extract was carried out by liquid chromatography, the amount of quercetin in the dry residue of extractive substances (derived from 10 g of dry material Gratiola officinalis) was 350 micrograms [24].

Experimental design (Design of the experiment)
The experiment was conducted according to “International Guiding Principles for Biomedical Research Involving Animals” [25]. The experiment was carried out in accordance with the guidelines for experimental (preclinical) study of new pharmacological substances and all applicable international, national, and/or institutional guidelines for the care and use of animals were followed. 40 male white laboratory rats weighing 150-450 grams were used; the model of flat skin wounds in the interscapular region in rats was reproduced under general anesthesia with the use of the preparation "Zoletil-100" (dissociative anesthetic, permitted in Russia) in the dosage of 15 mg/kg [26]. The wound was a section of rounded shape with the area of 100 mm². Epidermis and dermis were dissected up to subcutaneous fatty tissue. It was applied to the interscapular area by cutting out the plane on a pre-prepared stencil. Animals with experimental non-sterile wounds were divided into four groups by a random sampling method of 10 rats in each. The first experimental group contained rats with surface application of the extract to the wound. The second experimental group contained rats with intramuscular injection. Animals with oral injection were included in the third experimental group. All animals in experimental groups were given the extract in the dosage of 1 gram of extract per 1 kilogram of weight by different methods of application. The fourth group was a group of comparison which contained animals with non-sterile wounds, which had been treated daily with 3% hydrogen peroxide solution. Experiment continued until the wounds finally healed.

Wound area measurement
The wound healing dynamics was estimated by changing wound area according to the formula: S=A*B*t/4 (mm²), where A – width, B – length of the wound in mm. Measurements were made with an electronic caliper once in every 2 days from the beginning of the experiment. The healing rate of the wound was calculated by the formula C=(S2-S1)/S2*100%, where S2 was the initial area of the wound S1 was the area of the wound on the current day of measurement. When the areas of wounds in experimental animals were determined in each group, we calculated the average area (M±s, where M was the arithmetic mean, y was the standard deviation of the arithmetic mean). We tallied the percentage of wound area reduction from the initial size (the percentage of wound healing) and the rate of wound healing (the percentage of wound area reduction per day).

Microbiological research
We took a swab from the wound surface once in every 6 days to assess the microbial dissemination of the wound defect. After that we inoculated the material on the surface of the nutrient agar for the cultivation of microorganisms. The inoculations were incubated for 24 hours at 37 degrees Celsius. The actual quantitative bacterial dissemination (taking into account dilutions and the microbial count in the washing fluid) was estimated by the number of colony-forming units in 1.0 ml of contaminated wash)-CFU (colony-forming units)/ml.

Morphological research
To compare morphological characteristics of wounds, the rats were subjected to euthanasia sequentially as the wounds healed, but at each stage of the experiment the animals from the each group were subjected to euthanasia. At the end of the experiment, all the rats were euthanized, and samples of the repaired tissue were taken from the wound area for further investigation. One of
the morphological features that characterize the degree of activity of reparative and regenerative processes in wound healing was the thickness of the newly formed epidermis. In order to objectify the descriptive characteristics of the epidermis state, morphometric studies were carried out, i.e. the measures of its thickness at two points of the field of view (thickness of the new epidermis, thickness of the epidermis of the wound margins) were obtained from the histological specimen morphometry.

**Hematoxylin and eosin (H&E) staining**

Histological preparations were made according to standard methods. After fixation for 24 hours in 4% paraformaldehyde, the tissue blocks were dehydrated, embedded in paraffin, and cut into 4-µm-thick sections. The sections were dewaxed and stained with an H&E staining using standard procedures.

**Statistical analysis**

The data was statistically processed using the SPSS 17.0 software. The normal distribution of features was determined by Shapiro-Wilk test. Since the characteristics in the groups were found to be normally distributed, we chose Welch’s t-test for estimation of parameters. A difference between mean values with a probability of 95% (significance level *p*<0.05) by this method was determined at *p*≤1.96.

**Results**

**Macroscopic view of a wound defect change**

On the 3rd day of the experiment the average area of animal wounds in all groups was quite uniform. In the comparison group wounds in all groups was quite uniform. In the comparison group was the thickness of the newly formed epidermis. In order to measurement of parameters. A difference between mean values with a probability of 95% (significance level *p*<0.05) by this method was determined at *p*≤1.96.

Figure 1. Wound areas in dynamics.

The group with topical application fully completed healing by the 19th day of the experiment. In groups with intramuscular and oral injection of the extract the healing was fully completed within 21 days of the experiment. In the comparison group, full wound healing occurred on the 27th day of the experiment.

**Microbiological screening of a wound defect**

Evaluation of microbiological picture of wounds on the 3rd day of the experiment showed that microbial complications were not observed in the wounds of all groups of animals. On the 9th, 15th, 21st, 27th day after the operation the comparison group of animals revealed massive microbial insemination by bacteria belonging to the p. Staphylococcus in the amount of $3.0\pm0.05\times10^4$ CFU/ml. In the wounds of animals of experimental groups microbial insemination was at the level of $<1.0\pm0.05\times10^4$ CFU/ml. These results are shown in Figure 2.

**Histological research of a wound defect**

On the 19th day the histological research of skin samples of the wound surface in the comparison group determined the following changes in the epidermis: thinned corneal layer, the lack of clear differentiation of the layers, basal keratinocytes deformed and flattened. Cellular composition of spinous (stratum spinosum) and granular (stratum granulosum) layers was not differentiated. In the papillary layer of the dermis there were a small number of thin-walled blood vessels up to 45 microns in diameter. Most fibroblasts had a spindle shape and elongated hyperchromic nucleus, which indicated the functional inactivity of this cells’ subpopulation. The small number of new thin-walled vessels and a large number of functionally inactive fibroblasts indicated a low regenerative potential. Thickness ratio of the newly formed epidermis to the epidermis of the wound margins was 1:4.4. These results are shown in Figure 3A.
Figure 2. Assessment of microbial contamination of wound defects on the surface of HGM-agar on day 9.

The histological research of skin samples of the wound surface on the 19th day in the group with topical application of *Gratiola officinalis* extract demonstrated such epidermal changes as thinned horny layer, clear differentiation of the layers, active proliferation of the basal layer’s keratinocytes, the presence of a wide spinous layer. In the papillary layer of the dermis there were a large number of thin-walled blood vessels up to 55 microns in diameter, the presence of numerous proliferating fibroblasts and an increased number of macrophages and neutrophils. Thickness ratio of the newly formed epidermis to the epidermis of wound margins was 1:1.9. These results are shown in Figure 3B.

On the 21st day of the experiment, a thinned corneal layer was observed in the comparison group. There was no clearly defined differentiation of the epidermis layers. There were single thin-walled vessels in the papillary layer. A significant number of polygonal shaped proliferating fibroblasts and spindle shaped fibroblasts were observed. Thickness ratio of the newly formed epidermis to the epidermis of wound margins is 1:7.5. These results are shown in Figure 3C.

In the groups of oral and intramuscular injection of *Gratiola officinalis* extract there was a tendency to layer differentiation and active proliferation of keratinocytes of the basal layer on the 21st day of the experiment. The presence of numerous proliferating fibroblasts and increased number of macrophages, neutrophils and newly formed sebaceous glands were found. Thickness ratio of the newly formed epidermis to the epidermis of the wound margins in case of oral administration was 1:2.2 and in case of intramuscular administration – 1:2.9. These results are shown in Figures 3D and 3E.

**Morphometric research of the thickness of the newly formed epidermis and the epidermis of the wound margins**

As a result of histological morphometry, the parameters of the newly formed epidermis layer and the epidermis layer of the wound margins in all experimental groups exceeded the corresponding parameters of the comparison group. In comparison with the control group, the layer of the newly formed epidermis was 4.3 times thicker for the group with local application, twice thicker for the group with intramuscular administration and 2.4 times thicker for oral administration group. The indexes of epidermal thickness of the wound margins in the experimental groups also exceeded the corresponding indexes in the comparison group as follows: 1.9 higher for local application, 1.3 higher for intramuscular introduction and 1.8 higher for oral introduction. These results are shown in Table 2.
Discussion

*Gratiola officinalis* extract is a flavonoid containing composition. Flavonoids have a therapeutic application due to their anti-inflammatory, antifungal, antimicrobial, antioxidant and wound healing properties [27-29]. In addition, flavonoids and their derivatives are known to reduce lipid peroxidation, improving blood flow to blood vessels, and preventing or slowing the progression of cell necrosis. Therefore, it is assumed that any drug that inhibits lipid peroxidation increases the viability of collagen fibers by increasing the circulation and strength of collagen fibers, stimulating DNA replication and preventing cell damage [30-32].

When applied topically to the wound, aqueous solution of *Gratiola officinalis* extract shortens the wound healing time by 8 days in relation to the comparison group. This effect is caused by the direct influence of active components of the extract on the wound defect zone. The bacterial flora was eliminated, which eliminated the possibility of purulent complications. It is known from literature sources that flavonoids are able to activate and
have a modulating effect on Wnt signaling pathway, which is responsible for the differentiation of stem cells, as well as for the directed attachment of nerves to them. That, in turn, enhances the regenerative activity of tissue and activation of angiogenesis, which was demonstrated in the morphological study of samples of the dissected wound area (a large number of thin-walled vessels, cells of the phagocytic-macrophage system, a large number of proliferating fibroblasts).

In groups with oral and intramuscular administration of *Gratiola officinalis* extract there was an observation that the wound healing time was 6 days shorter in relation to the comparison group. This time delay, as compared to the group of local application, is due to such a characteristic feature of bioavailability of flavonoids as very slow removal of their metabolites from the body (half-life period – from 11 to 28 hours). This may contribute to the accumulation of metabolites in plasma at repeated injection. Quercetin and its metabolites contained in *Gratiola officinalis* extract are modulators of epidermal growth factor receptors, which stimulate cell growth and cell differentiation of epithelial cover, accelerating the process of early healing [14].

The antimicrobial activity assessment revealed a twofold decrease in microbial semination of wounds in all experimental groups relative to the comparison group. Due to the proven antimicrobial and anti-inflammatory properties, the *Gratiola officinalis* extract prevents the development of purulent complications of the wound surface [17].

Morphological signs of regeneration, which developed under the influence of *Gratiola officinalis* extract, revealed at histological examination of wound tissues, allowed the estimation of wound healing activity. Clear differentiation and thickness of layers of the newly formed epidermis, a large number of thin-walled vessels, actively proliferating fibroblasts indicate an active regeneration process. Thickness of the newly formed epidermis at the end of the experiment in all experimental groups more than twice exceeded this morphometric index of the comparison group, which confirms the literature data on the activation of signal pathways responsible for the innervation and differentiation of the epidermis stem cells.

**Limitations**

We used 40 white Wistar rats, 10 animals in each group, to study the effect of flavonoid-containing extract of *Gratiola officinalis* on the process of wound healing. This number represents a sufficient reference sample and allows reliable extrapolation of the study results. All applicable international, national, and/or institutional guidelines for the care and use of animals were followed. The advantages of the proposed new wound healing remedy based on the *Gratiola officinalis* extract include absence of toxicity, availability of raw materials from which the remedy is obtained and a wide range of other effects: anti-inflammatory, antimicrobial activity, ability to reduce the level of endogenous intoxication. The extract showed efficacy with oral, intramuscular and local application, which is demonstrated by the reduction of wound healing time – the time was reduced by 6 days with oral and intramuscular administration and by 8 days with local application, as well as morphological and morphometric signs of stimulation of tissue regeneration in all experimental groups, compared to the comparison group.

**Conclusion**

In summary, the aqueous solution of the dry extract of *Gratiola officinalis* has wound-healing activity due to the presence of a flavonoid — quercetin, which induces the regenerative potential of tissue. Antimicrobial properties of the extract prevent the development of purulent complications of the wound surface. The most effective route is local application of the product, where wound healing time is reduced by 8 days, intramuscular and oral administrations reduce healing time by 6 days. This extract may be of interest for specialists in the field of regenerative medicine, as an aid in the treatment of wound processes.
