SUMMARY

The generation of induced pluripotent stem cells (iPSCs) from differentiated cells following forced expression of OCT4, KLF4, SOX2, and C-MYC (OKSM) is slow and inefficient, suggesting that transcription factors have to overcome somatic barriers that resist cell fate change. Here, we performed an unbiased serial shRNA enrichment screen to identify potent repressors of somatic cell reprogramming into iPSCs. This effort uncovered the protein modifier SUMO2 as one of the strongest roadblocks to iPSC formation. Depletion of SUMO2 both enhances and accelerates reprogramming, yielding transgene-independent, chimera-competent iPSCs after as little as 38 hr of OKSM expression. We further show that the SUMO2 pathway acts independently of exogenous C-MYC expression and in parallel with small-molecule enhancers of reprogramming. Importantly, suppression of SUMO2 also promotes the generation of human iPSCs. Together, our results reveal sumoylation as a crucial post-transcriptional mechanism that resists the acquisition of pluripotency from fibroblasts using defined factors.

INTRODUCTION

The reprogramming of somatic cells into pluripotent cells using the classical set of transcription factors, OCT4, KLF4, SOX2, and C-MYC (OKSM) and conventional culture conditions (leukemia inhibitory factor, serum) usually takes several weeks and yields induced pluripotent stem cells (iPSCs) at extremely low frequencies (0.1%–3%) (Takahashi and Yamanaka, 2006). This observation suggests that reprogramming factors need to overcome undefined barriers that have been established by somatic cells to preserve cell identity and resist cell fate change. Identifying roadblocks to iPSC generation thus provides a valuable platform to dissect general principles of cell identity and cell fate change (Apostolou and Hochedlinger, 2013).

Previously identified barriers to reprogramming include regulators of cell cycle progression and senescence (e.g., P53, INK4A/ARF) (Krizhanovsky and Lowe, 2009), histone and DNA modifications (e.g., DNMT1, KDM2B, MBBD3) (Mikkelsen et al., 2008; Rais et al., 2013; Wang et al., 2011), as well as signaling pathways and epigenetic processes that can be targeted by small compounds (e.g., ascorbic acid, GSK3 inhibitor, DOT1L inhibitor) (Bar-Nur et al., 2014; Esteban et al., 2010; Onder et al., 2012; Silva et al., 2008). However, suppression of some of these barriers may enhance iPSC formation only under specific culture conditions (e.g., MBD3) (dos Santos et al., 2014; Rais et al., 2013), potentially limiting its usefulness in different cellular contexts. Moreover, manipulation of certain barriers causes permanent aberrations of the epigenome (e.g., DNMT1) (Jackson-Grusby et al., 2001), complicating its applications in a therapeutic setting.

More recently, unbiased small hairpin RNA (shRNA) screens have been performed during iPSC formation, leading to the identification of novel roadblocks to reprogramming (Qin et al., 2014; Samavarchi-Tehrani et al., 2010; Yang et al., 2014). Surprisingly, individual suppression of hits that emerged from these screens showed rather modest effects (2- to 4-fold enhancement) compared with the simultaneous suppression of multiple hits (5- to 10-fold enhancement). Furthermore, there was little overlap among independent screening efforts, suggesting that reprogramming may be restrained by additional, yet to be identified barriers. Indeed, our lab recently discovered the histone chaperone CAF-1 as a novel barrier to iPSC generation using a chromatin-focused shRNA screen (Cheloufi et al., 2015).

The goal of this study was to identify potent roadblocks to reprogramming by performing a serial genome-wide shRNA enrichment screen in combination with a well-defined transgenic reprogramming system. Our screening

strategy uncovered SUMO2 as a top-scoring hit, thus implicating protein sumoylation as a mechanism that effectively resists transcription factor-induced pluripotency.

RESULTS

Serial shRNA Screen for Roadblocks to Reprogramming

To identify roadblocks to iPSC formation in an unbiased manner, we combined a well-defined transgenic reprogramming system with a genome-wide shRNA library targeting 18,464 genes with 60,642 hairpins. We utilized murine embryonic fibroblasts (MEFs) carrying a doxycycline (dox)-inducible polycistronic cassette encompassing the open reading frames for Oct4, Klf4, Sox2, and c-Myc (OKSM) in the Col1a1 locus, the M2-rTA transactivator in the Rosa26 locus, and an EGFP reporter in the endogenous Pou5f1 (Oct4) locus (Stadtfeld et al., 2010). We will refer to these transgenic MEFs as “reprogrammable cells” and the genotype as “Col1a1-tetOP-OKSM; R26-M2rtTA; Oct4-GFP.” The shRNA library was generated by cloning shRNAs into the pHAGE-Mir lentiviral vector carrying a puromycin resistance gene and a turbo red fluorescent protein (tRFP) reporter (Meerbrey et al., 2011; Schlabach et al., 2008) (see Experimental Procedures for details). Transduction of reprogrammable MEFs with an identical empty vector gave rise to Oct4-GFP+, tRFP+ iPSC colonies upon exposure to dox, albeit at slightly lower frequencies than uninfected cells (Figures 1A and 1B; data not shown), demonstrating the feasibility of an shRNA screen using these cells and vector system.

To identify shRNAs that strongly enhance reprogramming with low background signal from passenger shRNAs, we devised a pooled screening strategy using serial enrichment of hairpin libraries. In brief, we infected reprogrammable MEFs with the pooled shRNA library 2 days before dox induction to ensure effective suppression of targets prior to initiation of reprogramming. After 10 days of OKSM expression, dox was withdrawn for 4 days to select for stably reprogrammed, transgene-independent colonies, followed by purification of emerging Oct4-GFP+ cells by flow cytometry (Figure 1C). Enriched hairpins were amplified by PCR from genomic DNA and subsequently recloned into the original viral backbone before initiating another round of viral transduction and reprogramming. We performed five rounds of reprogramming and shRNA enrichment before focusing on candidates (Figures 1D and 1E). Parallel cultures of reprogrammable MEFs were exposed to dox alone or transduced with the viral library in the absence of dox before extracting genomic DNA (Figures 1E and S1); these samples served as controls for possible passenger hairpins that became passively enriched in expanding iPSC colonies or hairpins that merely affected the growth of uninduced reprogrammable MEFs. Library representation was then determined in all samples by deep (Illumina) sequencing of genomic DNA. Notably, we detected a gradual reduction of library complexity and a progressive accumulation of specific shRNA vectors during the five rounds of screening, suggesting enrichment of biologically meaningful hairpins (Figures 1F and 1G).

SUMO2 Emerges as a Top-Scoring Candidate Barrier to Reprogramming

We next applied stringent criteria to call hits based on the number of normalized reads and the cumulative fold change of shRNAs across all rounds of reprogramming relative to controls (Figure S1). Analysis of shRNAs that were consistently enriched revealed several candidate barriers to reprogramming including FGF5, SMPDL3A, and SUMO2 (Figures 1F–1H). Of note, some of the top-scoring shRNAs affected pathways that were previously shown to block reprogramming, including members of the FGF/FGFR and OLFR families (Dejeosez et al., 2013; Qin et al., 2014). A complete list of candidates with associated cumulative enrichment scores is shown in Table S1. Of the 27 validated shRNAs, seven showed a more than 2-fold increase in iPSC formation (Gstt4, Gm719, Sqrdl, Dnmt3a, BTBD10, Smpld3a, Sumo2) (Figure 1H), with Sumo2 shRNA exhibiting the strongest phenotype.

Given the prominent effects on reprogramming of shRNAs targeting Sumo2, we will focus on this gene for the remainder of this article. SUMO2 (small ubiquitin-like modifier 2) is a ubiquitin-related protein that can be covalently attached to proteins as a lysine-linked monomer or polymer. This post-translational modification, lysine sumoylation, controls the stability, activity, and localization of hundreds of proteins and has been implicated in a number of biological processes including DNA replication and repair, heterochromatic gene silencing, and signal transduction (Flotho and Melchior, 2013).

Suppression of SUMO2 Promotes Reprogramming without Compromising Proliferation or Pluripotency

Using more quantitative reprogramming assays, we found that suppression of SUMO2 increases the number of transgene-independent alkaline phosphatase-positive (AP+)...
Figure 2. Suppression of SUMO2 Robustly Enhances and Accelerates Reprogramming

(legend continued on next page)
iPSC-like colonies and the fraction of Oct4-GFP* cells by 7- to 8-fold (16% Oct4-GFP* cells with Sumo2 shRNA; 2% with control shRNA at day 8) (Figures 2A–2D). We were able to recapitulate enhanced reprogramming with six independent shRNAs as well as small interfering RNA (siRNA) pools targeting Sumo2, documenting the consistency of the observed phenotype using either permanent or transient knockdown approaches (Figures 2C, 2D, and S2A). Expression of Sumo2 shRNAs led to reduced Sumo2 transcript levels as well as a decrease of free and conjugated SUMO2 protein levels, demonstrating specificity of the knockdown vector and diminution of global sumoylation levels (Figures 2E and S2B). Considering that sumoylated KLF4 reportedly inhibits cellular reprogramming (Tahmasebi et al., 2013), we next determined whether SUMO2 suppression leads to reduced KLF4 sumoylation. However, we failed to detect obvious differences in KLF4’s sumoylation status in cells expressing OKSM and Sumo2 shRNAs in a preliminary experiment, suggesting that the effect of SUMO2 on iPSC formation may involve other targets (Figure S2C). Moreover, forced expression of SUMO2 during iPSC generation (Figure S2D) was insufficient to block reprogramming (data not shown), indicating that downregulation of SUMO2 may not be required to attain pluripotency. Indeed, we found that endogenous Sumo2 mRNA levels were comparable between MEFs and iPSCs and barely changed during the reprogramming process (Figure 2F). These results suggest that SUMO2 may play independent roles in somatic and pluripotent cell types. iPSCs generated with Sumo2 shRNAs could be stably propagated over many passages and gave rise to well-differentiated teratomas, demonstrating that suppression of SUMO2 does not compromise the self-renewal or pluripotency of iPSCs (Figure S3A).

To complement the aforementioned marker-based assays of reprogramming with a functional readout, we determined whether suppression of SUMO2 could promote the formation of transgene-independent iPSC colonies after reduced pulses of OKSM expression (Figure 2G). Indeed, we found that knockdown of SUMO2 yielded transgene-independent iPSC colonies after only 4–5 days of OKSM expression, whereas stable iPSC colonies only emerged between days 6 and 8 in controls, consistent with previous findings (Stadtfeld et al., 2008) (Figure 2H). In agreement with this observation, we detected a significant upregulation of key embryonic stem cell (ESC)-associated transcripts (e.g., Nanog, Nrsal2, Salh4) and epigenetic regulators (e.g., Dnmt3b and Tet1) as well as a downregulation of MEF-associated transcripts (e.g., Twist2, Fgf18, Meox2) in cells expressing OKSM and Sumo2 shRNAs at day 6 of reprogramming relative to a non-targeting shRNA control (Figures 2I and 2J). Critically, knockdown of SUMO2 had no discernable effect on cell proliferation or apoptosis of bulk cultures, thus excluding the possibility that the observed phenotype is due to accelerated growth or reduced cell death (Figures S3B and S3C). Together, these results demonstrate that both transient and constitutive suppression of SUMO2 markedly enhances and accelerates the formation of iPSCs from somatic cells.

**SUMO2 Suppression Acts during Early-to-Mid Stages of Reprogramming**

To understand how SUMO2 suppression influences the dynamics of iPSC formation, we utilized surface markers and a reporter allele to distinguish between early, mid, and late stages of reprogramming. We previously showed that cells undergoing successful reprogramming initially upregulate SSEA1 (early stage), followed by sequential activation of EPCAM (mid stage) and Oct4-GFP (late stage) (Polo et al., 2012; Stadtfeld et al., 2008) (Figure 3A). SUMO2 depletion had no pronounced effect on the earliest intermediates of reprogramming, as shown by comparable fractions of SSEA1* and EPCAM* cells at day 3 relative to controls (Figures 3B, 3C, and S4). However, we noticed a 3-fold increase in the fraction of SSEA1* cells and a 5-fold increase in the fraction of EPCAM* cells by day 5 as well as an 8-fold increase in the fraction of Oct4-GFP* cells by day 8 of reprogramming. These data indicate that SUMO2 suppression facilitates early-to-mid stages of iPSC formation based on surface marker expression in bulk cultures.

To corroborate the notion that SUMO2 suppression promotes early-to-mid stages of reprogramming, we determined iPSC colony formation efficiencies after transfecting reprogrammable MEFs with siRNAs against Sumo2 either once (on day 0) or twice (on days 0 and 3) (Figures 3D and 3E). iPSC colony formation was essentially the same when SUMO2 was suppressed initially or continuously during a 6-day reprogramming period, suggesting that early SUMO2 suppression is sufficient to elicit enhanced reprogramming. Consistent with the acceleration of reprogramming upon suppression of SUMO2, we find that MEFs expressing OKSM and Sumo2 shRNAs for only 6 days are molecularly most similar to advanced stages of reprogramming (day 9 and day 12 intermediates) using a previous expression time course (Polo et al., 2012), whereas MEFs expressing OKSM and a control shRNA are most similar to day-6 intermediates, as expected (Figure 3F).

---

(1) Scatterplot comparing microarray data (log2 values) of day-6 reprogramming intermediates expressing indicated shRNAs. Representative upregulated pluripotency genes are shown in red whereas downregulated somatic genes are shown in green.

(2) Normalized expression levels of representative pluripotency-associated and MEF-associated genes in indicated samples at day 6 of OKSM expression. Data obtained from one experiment. RepMEFs, reprogrammable MEFs; ESCs, embryonic stem cells.
Collectively these phenotypic, functional, and molecular data suggest that SUMO2 suppression accelerates early-to-mid stages of reprogramming, ultimately leading to a strong increase in the number of Oct4+ transgene-independent iPSCs.

SUMO2 Suppression Acts Independently of C-MYC and in Parallel with Small Molecules

We next investigated whether exogenous C-MYC expression is required for the enhancement of iPSC formation by Sumo2 shRNAs. To this end, we derived reprogrammable MEFs from mice carrying the Col1a1-tetOP-OKS-mCherry allele (lacking the c-Myc transgene) in combination with the R26-M2rtTA allele (Figure 4A). Exposure of these MEFs to dox alone gave rise to extremely few, if any, AP+ colonies after 9–21 days of OKS expression, and no Oct4-GFP+ cells could be detected by day 9 of reprogramming (Figures 4B–4D). By contrast, depletion of SUMO2 in these cells using transient transfection of siRNA pools yielded iPSC colonies and stable Oct4-GFP+ cells by flow cytometry as early as 9 days after OKS induction. We conclude that suppression of SUMO2 enhances reprogramming independently of exogenous C-MYC expression, thus enabling iPSC formation in the absence of this potent oncogene.

To determine whether SUMO2 suppression acts in parallel with small molecules that were previously shown to enhance reprogramming, we treated reprogrammable cells harboring shRNAs against Firefly or Sumo2 shRNAs with doxycycline in the presence or absence of ascorbic acid (AA) (Esteban et al., 2010), a DOT1L inhibitor (DOT1Li) (Onder et al., 2012), and a GSK3 inhibitor (GSK3i) (Silva et al., 2008). Consistent with previous reports, we found that exposure of reprogrammable cells to each of these compounds significantly enhanced the generation of AP+ iPSC colonies, with combined AA/GSK3i treatment (AGi) exhibiting the strongest effect (Bar-Nur et al., 2014). Strikingly, SUMO2 depletion alone even surpassed the effect of AGi exposure based on AP+ colony formation.
on the reprogramming process and suggest that the sumoylation pathway may act in parallel to previously described facilitators of iPSC formation, including AA and inhibitors of H3K79 methylation and GSK3/WNT signaling.

**Generation of iPSCs after as Little As 38 Hours of OKSM Expression**

Given the additive effect between SUMO2 suppression and small molecule enhancers of reprogramming, we asked whether this combination treatment would allow us to further reduce the minimal time period of OKSM expression required to produce stable transgene-independent iPSCs. We used early passage reprogrammable MEFs (passage 2) carrying two copies of each of the *Col1a1-tetOP-OKSM* and *R26-M2rtTA* alleles to achieve optimal reprogramming efficiencies (Stadtfeld et al., 2010). MEFs exposed to DOT1Li, GSK3i, and AA required only 72 hr of OKSM expression to produce the first dox-independent AP+ iPSCs, which is faster than any previously reported protocol (Figures 5A and 5B). Remarkably, suppression of SUMO2 further reduced this time window to 38 hrs. Emerging iPSC colonies activated the endogenous Oct4-GFP reporter, expressed endogenous NANOG, OCT4, and SOX2, gave rise to well-differentiated teratomas, and supported the formation of coat-color chimeras, indicating acquisition of an authentic iPSC state (Figures 5C–5F). Analysis of global transcriptional patterns of these iPSCs further revealed a remarkable similarity with either iPSCs generated after 10 days of OKSM expression or with an established ESC line, suggesting that abbreviated OKSM expression in the presence of chemicals and *Sumo2* shRNAs does not compromise the pluripotency program (Figures 5G–5I and 5S). These results show that 1–2 days of OKSM expression are sufficient to produce stable, pluripotent iPSCs when SUMO2 expression is transiently suppressed under optimal culture conditions.

Finally, we tested whether suppression of SUMO2 also enhances human reprogramming. To this end, we infected human dermal fibroblasts with vectors expressing *OKSM* and either SUMO2 or *FIREFLY (FF)* shRNAs and measured the formation of AP+ colonies at day 21 (Figures 5J–5L). Consistent with our observations in the mouse system, we find that suppression of SUMO2 increases the formation of human iPSC-like colonies by 4- to 6-fold. We also noticed that human iPSC-like colonies expressing *SUMO2* shRNAs formed earlier than controls, suggesting acceleration of reprogramming (data not shown). Thus, sumoylation is a conserved reprogramming barrier across murine and human somatic cells.

**DISCUSSION**

Here, we identified SUMO2 as a potent roadblock to iPSC generation by combining a well-defined transgenic numbers (Figure 4E). Moreover, suppression of SUMO2 further enhanced iPSC formation in the presence of either ascorbate, GSK3i, or DOT1Li (Figure 4F). These results underscore the strong effects of SUMO2 suppression alone...
Figure 5. Generation of iPSCs after as Little as 38 Hours of OKSM Expression and Human Reprogramming Experiments

(A) Treatment with ascorbic acid (AA), DOT1L inhibitor (DOT1Li), and GSK3 inhibitor (GSK3i) facilitates the recovery of transgene-independent AP⁺ iPSC colonies from control and Sumo2 siRNA transfected MEFs after 72 hr of OKSM expression.

(B) Quantification of data shown in (A) using three biological replicates (mean ± SD).

(C) Suppression of SUMO2 enables generation of Oct4-GFP⁺ transgene-independent iPSCs after 38 hr of OKSM expression in the presence of the indicated small molecules.

reprogramming system with a genome-wide shRNA screening approach. In contrast to previous shRNA or siRNA screens conducted during iPSC formation, we employed a serial shRNA enrichment strategy, which may reduce the number of false-positive hits and allow for selection of shRNAs with stronger phenotypes. Indeed, suppression of a top candidate, SUMO2, markedly enhanced and accelerated iPSC formation compared with individual hits that emerged from previous large-scale screens or candidates that were selected based on gene-expression differences between somatic and pluripotent cells. In agreement with the notion that the expression of barrier genes does not necessarily have to be different between MEFs and iPSCs, we found that *Sumo2* mRNA levels do not dramatically change during reprogramming. To our knowledge, iPSC formation after 38 hr of OKSM expression represents the shortest time period that has been reported to obtain stably reprogrammed cells from fibroblasts. In addition to SUMO2, our screen uncovered a number of other candidate barriers to iPSC formation, which provide a useful resource for future mechanistic studies of the reprogramming process.

While SUMO2 has not previously been recognized as a roadblock to reprogramming, a recent report suggested that knockdown of the upstream SUMO-conjugating enzyme UBC9 blocks iPSC formation (Tahmasebi et al., 2014). Several reasons may account for the apparent discrepancy between our studies. For example, UBC9 knockdown is expected to inhibit SUMO1, SUMO2, and SUMO3, which may be toxic to cells, whereas SUMO2 depletion may be tolerated by cells owing to compensation by SUMO1 and/or SUMO3. In support of this idea, *Ubc9* deletion in vivo causes a more severe phenotype compared with individual deletion of *Sumo1*, *Sumo2*, or *Sumo3* (Wang et al., 2014). Furthermore, knockdown of UBC9 in ESCs reportedly triggers differentiation (Tahmasebi et al., 2014). Considering that the same constitutive knockdown vectors were used to assess UBC9’s role in ESC self-renewal and reprogramming, it is possible that a potential increase in the number of iPSCs was overlooked due to their immediate loss through differentiation. Indeed, a recent shRNA screen conducted during iPSC formation with retroviral vectors, which become silenced in iPSCs, identified UBC9 as a potent reprogramming barrier (Chehroudh et al., 2015).

Mechanistically, SUMO2 depletion may enhance iPSC formation by derepressing epigenetically silenced pluripotency loci (Poleshko et al., 2014; Yang et al., 2015) as well as histone and protein biosynthesis genes important for cellular growth and proliferation (Neyret-Kahn et al., 2013). Consistently, we find that key pluripotency genes and epigenetic regulators are expressed more robustly in SUMO2-depleted reprogramming intermediates compared with controls. In addition, SUMO2 suppression may contribute to iPSC formation by directly modulating certain pluripotency factors during iPSC generation. In agreement with this view, sumoylation of SOX2 and KLF4 reportedly impairs transcriptional activity and compromises pluripotency (Tahmasebi et al., 2013; Wu et al., 2012). Moreover, overexpression of sumoylation-deficient variants of these transcription factors slightly enhances reprogramming into iPSCs, although the reported effects were subtle compared with the phenotype reported here. Considering these observations and our preliminary finding that KLF4 is not differentially sumoylated upon suppression of SUMO2, we surmise that SUMO2 acts at multiple levels to resist the acquisition of pluripotency rather than to control the activity or stability of a single protein target. It should be informative to identify relevant SUMO2 targets in MEFs and iPSCs using recently developed proteomics and chromatin immunoprecipitation sequencing (Becker et al., 2013; Neyret-Kahn et al., 2013) approaches.

Our findings may have practical implications for basic science and cell therapy. The ease with which SUMO2 can be inhibited using transient siRNA delivery should facilitate the mechanistic dissection of the reprogramming process in more homogeneous cell cultures. The observation that SUMO2 depletion increases human iPSC generation, cooperates with small-molecule enhancers of reprogramming, and negates the need for exogenous C-MYC expression, may further facilitate the efficient and safe generation of patient-specific iPSCs from rare donor cells.

**EXPERIMENTAL PROCEDURES**

**Tissue Culture and Virus Production**

Reprogrammable mouse embryonic fibroblasts (RepMEFs) were derived from embryonic day 13.5–15.5 embryos carrying either the *Col1a1-tetOP-OKSM* or *Col1a1-tetOP-OKS-mCherry* alleles in combination with the *Rosa26-M2rtTA* alleles (Bar-Nur et al., 2014; Stadtfeld et al., 2010). Reprogramming was initiated by adding 20 ng/ml doxycycline (dox) (Sigma, catalog #D9891-25G) to RepMEFs and, where indicated, 25 μg/ml L-AA (Sigma, catalog #A4544-25G), 3 μM GSK3 inhibitor (CHIR99021, Stemgent, catalog #04-0004), ALK5 inhibitor (Calbiochem, catalog #616452),

(K) Reprogramming efficiency of cells characterized in (J) as measured by the number of AP⁺ colonies per 60,000 plated fibroblasts. Values represent means from three biological replicates ± SD.

(L) Representative images of bright-field and AP⁺ colonies obtained with *SUMO2* and *FIREFLY* shRNA vectors after 14 and 21 days of OKSM expression.
1 μM MEK inhibitor (PD0325901, Stemgent, catalog #04–0006), or DOT1L inhibitor (generous gift from Dr. Peter Brown). Viral transductions, using pHage or pGIPZ vectors in combination with packaging plasmids psPax2 and pDM2.G, were performed by spin infection for 30 min at 2,150 rpm at room temperature. The following shRNA seed sequences were used for mouse experiments: pHage shRNA (shSumo2 #1), ATAAAGACGATGAGCATGCC; pGIPZ (shSumo2 #2–7; Dharmacon); #2 (V2LMM_2701), TTCTGGAG TAAATGACGAG; #3 (V2LMM_5118), TAAATGACGATGACGATG; #4 (V3LMM_496391), TGTGGTAGACTCCAGTCT; #6 (V3LMM_496391), TGGACGACTGCTGACTCC; #7 (V3LMM_496396), AATCTTAACTGACCACACA. Transfections of RepMEFs with 1.5 μl siRNAs (esiRNA technology, Sigma; Sumo2: EMU095391, Renilla: EHURLUC) were performed in 12-well plates using Lipofectamine 2000 and Opti-MEM (Life Technologies) according to the manufacturer's instructions. For human reprogramming experiments, BJ fibroblasts were first infected with control or SUMO2 pGIPZ shRNA (V3LHS_388696 and V3LHS412780; GE Dharmacon) viruses. Two days later, cells were infected with the human pHAGE-STEMCCA virus (Sommer et al., 2012) to initiate reprogramming. Cells were replated in fibroblast medium (DMEM and 10% FBS) and cultured for 4 days. Medium was then switched to a 1:1 mixture of fibroblast medium (DMEM and 10% FBS) and human ESC medium (E8; STEMCELL Technologies) for another 2 days, and finally to 100% human ESC medium. Cells were stained for alkaline phosphatase activity (Stemgent), and AP+ iPSCs were counted.

**Immunofluorescence Analysis**

iPSC lines (passage 6 or higher) were seeded in a 24-well plate at a low density. Once small colonies emerged, wells were washed with 1× PBS and fixed by a 5- to 10-min incubation in 10% formalin at room temperature. After washes in 1× PBS, cells were blocked in 1× PBS containing 2% BSA and 0.1% Triton X-100. Primary and secondary antibodies were diluted in blocking solution at a concentration of 1:200 and added for 1 hr at room temperature or overnight at 4°C. Primary antibodies were anti-NANOG (Abcam, catalog #AB80892), anti-SOX2 (Santa Cruz Biotechnology, catalog #Sc-17320), anti-OCT4 (Santa Cruz, catalog #Sc-8628); secondary antibodies were donkey anti-goat immunoglobulin G (IgG) or donkey anti-rabbit IgG Alexa Fluor 546-conjugated antibodies (Life Technologies). After two washes in 1× PBS, cells were immobilized on slides in mounting medium containing DAPI (Vectorshield, Vector Labs) and analyzed.

**RNA Expression Analysis**

For global gene-expression analysis, total RNA was isolated from indicated samples using an RNeasy Mini Kit (Qiagen) and analyzed by Affymetrix microarray chips. The raw microarray expression signals in the CEL files were normalized using the Affymetrix Expression Console software and robust multiaarray averaging normalization. For qPCR analysis, Brilliant III SYBR-Green-based master mix was used according to the manual (Agilent), following RNA isolation (RNeasy kit, Qiagen) and reverse transcription (Transcriptor First Strand cDNA Synthesis Kit, Roche) of Sumo2 or control knockdown samples 2 days after initiation of reprogramming. Samples were run in triplicate on the Lightcycler 480 (Roche). Primer sequences for qPCR were as follows: Sumo2 (forward), AAG GAAAGGATCAAGACTGAGAA; Sumo2 (reverse), CGGAATCT GATCTGCCTCATTT; GAPDH (forward), AGGGCGTGTTGACCCAGATTG; GAPDH (reverse), TGGACCATGATGTGGAGCT.

**Scatterplot**

Microarray gene-expression measurements for samples containing Sumo2 or Firefly shRNA for 6 days were obtained. For genes with more than one probe, the average of all probes was used. These expression measurements were plotted (on a log2 scale), with Firefly expression on the x axis, Sumo2 knockdown expression on the y axis, and each point representing a gene. Genes falling outside of the dashed lines have a fold change of greater than 1.5 between Sumo2 knockdown and Firefly. Some key genes were highlighted, with those being upregulated in Sumo2 knockdown colored red, and those downregulated colored green.

**Correlation Matrix**

Previously published microarray gene-expression measurements representing stages of reprogramming were obtained from GEO (GSE42379). The following samples were used: KH2-MEF_m2,
for an additional 4 days. Cells were harvested, pooled, and purified

AA and dox) for 10 days, and in dox/ascorbic acid-free ESC media

con) in reprogramming medium (ESC medium supplemented with

Western Blot Analysis

Protein lysates were run on 4%-20% Mini Protein TGX gels (Bio-

Rad), blotted onto Immobilon-P membrane (EMD Millipore),

and incubated with anti-SUMO2 antibody ab3742 (Abcam) and anti-RAN antibody 610341 (BD) for western blot analysis. We

used anti-KLF4 antibody AF3158 (R&D Systems), anti-OCT4 anti-

body 11,263-1-AP (ProteinTech), and anti-SUMO2 antibody

ab81371 (Abcam) for immunoprecipitation experiments.

Generation of pHAGE-Mir Vector

The pHAGE lentiviral backbone was released from pHAGE-EF1a-
egFP-W vector (kindly provided by Dr. Richard Mulligan’s labora-
tory) using NotI + BamHI. tRFP was PCR amplified from

MiSeq instrument, using a custom sequencing primer: mir30-

2.5 µg genomic DNA template, 200 µM dinucleotide triphos-

phates (dNTPs), 400 nM of each PCR primer (pHAGE-Mir-PCR,

5’-GCAAACTGGGGCACAGATGATGCGG; BC1R-L, 5’-GGCCTCC

CCTACCCGTTAGA), 1× Q5 reaction buffer, 1× Q5 high GC buffer,

and 0.5 µl Q5 polymerase (NEB). PCR was performed with the

following program: 94°C for 4 min, 35 cycles of (94°C 30 s, 60°C 30 s, 72°C 45 s), and 72°C for 10 min. PCR products

(~700 bp) for each sample were pooled, ethanol precipitated, re-

suspended, and gel purified using the QIAquick Gel Extraction

Kit (Qiagen). The purified shRNA PCR products were used to (1)

generate sublibraries for the next round of shRNA library screens and (2) generate sequencing libraries for Illumina sequencing.

For sublibrary generation, the purified PCR product was digested with NotI and MluI, and the ~400-bp fragment that contains the

shRNAs was gel purified. Separately, the pHAGE-Mir plasmid was also digested with NotI and MluI to recover the ~9 kb vector back-

bone. The purified shRNA fragment (25–50 ng) and the vector backbone (125–250 ng) were ligated in a 5 µl ligation reaction using

NEB T4 ligase. A 1 µl ligation reaction was used to transform 20 µl Electromax competent cells DH10b (Life Technologies) with
electroporation. One microliter of the transformation reaction was

the following program: 94°C for 2–3 hr. The bacteria were collected and

cultured in 300 ml LB-carbenicillin (100 µg/ml) plates and
grown overnight at 37°C. At least 100× coverage was needed to

maintain the representation of the library (i.e., colony number =

100 × the number of shRNAs in the library). When necessary, the entire ligation reaction may be used for transformation in mul-
tiple electroporation reactions to increase the number of colonies.

The next day, lawns formed on the two 15 cm plates were scraped off and cultured in 300 ml LB-carbenicillin (100 µg/ml) plates

and grown at 30°C for 2–3 hr. The bacteria were collected and the cloned sublibary DNA was extracted by the Genelute Maxi-

prep kit (Sigma).

For Illumina sequencing, the purified shRNA PCR product was used as template for another round of PCR: 500 ng purified shRNA

PCR product, 200 µM dNTPs, 2 µM each PCR primer (p5 and p7), 1× Q5 reaction buffer, 1× Q5 high GC buffer, and 1 µl Q5 polymerase

(NEB) in 100 µl PCR reaction buffer. PCR was performed with the

following program: 94°C for 4 min, two cycles of (94°C 30 s, 50°C 20 s, 72°C 30 s), 20 cycles of (94°C 30 s, 60°C 20 s, 72°C 30 s), and 72°C for 10 min. PCR products (~120 bp) were gel puri-

fied using the QIAquick Gel Extraction Kit (Qiagen). Gel-purified

products were submitted for Illumina sequencing on the Illumina

MiSeq instrument, using a custom sequencing primer: mir30-

EcoRI: 5’-TAGCCCTTGAATTCCGAGGCAGTAGGCA.
PCR primers: p5-miSeq, 5'-ATGATAACGCGACCACCGAGATC TACACCTAAGTGGCCCTCCTGAATTC; p7-miSeq-1, 5'-CAAGCA GAAGCGCCATACGAGTGAATGGAAGCCACAGATGTA; p7- miSeq-2, 5'-CAAGCAGAAGACGCGTACCGACACTGAGTGAAG CCACAGATGTA; p7-miSeq-3, 5'-CAAGCAGAAGAGCCACAGATGTA; and p7-miSeq-4, 5'-CAAG GCAGAAGACGCCATACGAGGCTATGGAAGCCACAGATGTA. Different p7 primers were used for multiplexing purposes.

Single-end 51-bp reads were obtained using the Illumina HiSeq or MiSeq instrument. The reads are expected to have an initial 22 nucleotides that identify the shRNA, followed by a constant region that is the same for all shRNAs and a two-nucleotide barcode to identify the sample. Reads that contain perfect matches at the following six nucleotides were first extracted from the sequencing data: the two nucleotides adjacent to the initial 22 base sequence and the two nucleotides adjacent to the barcode on both sides. The shRNAs were then identified by requiring an exact match of the 22 nucleotides to the sequences in the shRNA library annotation file. The samples were identified by the two-nucleotide barcodes.

The total number of reads that were identified for each shRNA, sample, and round were counted. The counts were normalized to be directly comparable between samples and rounds by first dividing by the total number of counts for that sample and round, and then multiplying by the total number of shRNAs in the initial library. A pseudocount of 1 was added to each normalized count to downweight enrichment derived from low-read counts and to avoid division by zero in calculating fold changes.

The enrichment for each shRNA in each round was calculated as the log2 fold change of the Oct4-GFP* normalized counts over the maximum of the normalized counts of the controls (T0, No-Dox, and Oct4-GFP* cells). The cumulative enrichment for each shRNA in each round was calculated as the sum of the log2 fold changes for that round and all previous rounds. The overall enrichment of each shRNA was defined as the maximum of the cumulative enrichment scores among all rounds.

The heatmap for Figure 1G was plotted using the cumulative enrichment scores. Only shRNAs that have at least one read in the Oct4-GFP* sample in at least two rounds were used in the plot, resulting in a total of 23,853 shRNAs.

ACCESSION NUMBERS

Microarray expression data are available at the Gene Expression Omnibus database under accession number GEO: GSE76699.

SUPPLEMENTAL INFORMATION

Supplemental Information includes five figures and one table and can be found with this article online at http://dx.doi.org/10.1016/j.stemcr.2016.02.004.

AUTHOR CONTRIBUTIONS

M.B., B.D.B., N.M., S.J.E., G.H., and K.H. planned the experiments; M.B. and G.H. performed the serial enrichment screen, validated and characterized hits; B.D.B. conducted all bioinformatics analyses with assistance from Y.D. and D.C.F.; B.I. performed sumoylation experiments; O.B.N. generated teratomas and helped with array analysis; J.B. generated chimeric mice; L.W. performed human reprogramming experiments; E.A. provided tetOP-Oks MEFs; S.C. shared unpublished information; M.B., B.D.B., G.H., and K.H. wrote the manuscript.

ACKNOWLEDGMENTS

We thank Laura Prickett, Kat Foz-Donahue, and Meredith Weglarz of the CRM Flow Cytometry core facility and all K.H. and G.H. lab members for advice and discussions. We are grateful to Dr. Peter Brown for providing the DOT1L inhibitor, and Dr. Jianping Jin for providing the SUMO2 entry vector. We thank Dr. Mehrnaz Ghazviniz for help with human reprogramming experiments. We thank our animal facility for the care of mice; all mouse experiments have been approved by the Institutional Animal Care and Use Committee. M.B. was supported by a Boehringer Ingelheim Fonds predoctoral fellowship, O.B.N. by a MGH Tosteson fellowship, J.B. by the NIH (1F32HD078029-01A1) and S.C. by the PRCRP at the Department of Defense (CA 120212). This work was supported by grants from the NIH (GM44664 and AG011085) to S.J.E.; S.J.E. is an Investigator with the Howard Hughes Medical Institute. G.H. was supported by the Intramural Research Program at the National Institute of Environmental Health Sciences (Z01ES102745). Support to K.H. was from the Gerald and Darlene Jordan Endowment, the NIH (HD058013), and an Early Career Award from the Howard Hughes Medical Institute.
