Equal Bits: Enforcing Equally Distributed Binary Network Weights

Yunqiang Li*, Silvia L. Pintea* and Jan C. van Gemert

Abstract

Binary networks are extremely efficient as they use only two symbols to define the network: \{+1, −1\}. One can make the prior distribution of these symbols a design choice. The recent IR-Net of Qin et al. argues that imposing a Bernoulli distribution with equal priors (equal bit ratios) over the binary weights leads to maximum entropy and thus minimizes information loss. However, prior work cannot precisely control the binary weight distribution during training, and therefore cannot guarantee maximum entropy. Here, we show that quantizing using optimal transport can guarantee any bit ratio, including equal ratios. We investigate experimentally that equal bit ratios are indeed preferable and show that our method leads to optimization benefits. We show that our quantization method is effective when compared to state-of-the-art binarization methods, even when using binary weight pruning.

Our code is available at https://github.com/liyunjianggyn/Equal-Bits-BNN

1 Introduction

Binary networks allow compact storage and swift computations by limiting the network weights to only two symbols \{−1, +1\}. In this paper we investigate weights priors before seeing any data: is there a reason to prefer predominately positive bit weights? Or more negative ones? Or is equality preferable? Successful recent work (Qin et al. 2020b) argues that a good prior choice is to have an equal bit-ratio: i.e. an equal number of +1 and −1 symbols in the network. This is done by imposing an equal prior under the standard Bernoulli distribution (Qin et al. 2020b; Peters and Welling 2018; Zhou et al. 2016). Equal bit distributions minimize information loss and thus maximizes entropy, showing benefits across architectures and datasets (Qin et al. 2020b). However, current work cannot add a hard constraint of making symbol priors exactly equal, and therefore cannot guarantee maximum entropy.

Here, we propose a method to add a hard constraint to binary weight distribution, offering precise control for any desired bit ratio, including equal prior ratios. We add hard constraints in the standard quantization setting (Bulat and Tzimiropoulos 2019; Qin et al. 2020b; Rastegari et al. 2016) making use of real-valued latent weights that approximate the binary weights. We quantize these real-valued weights by aligning them to any desired prior Bernoulli distribution, which incorporates our preferred binary weight prior. Our quantization uses optimal transport (Villani 2003) and can guarantee any bit ratio. Our method makes it possible to experimentally test the hypothesis in (Qin et al. 2020b) that equal bit ratios are indeed preferable to other bit ratios.

We baptize our approach with equal bit ratios: \textit{bi-half}. Furthermore, we show that enforcing equal priors using our approach leads to optimization benefits by reducing the problem search-space and avoiding local minima.

We make the following contributions: (i) a binary network optimization method based on optimal transport; (ii) exact control over weight bit ratios; (iii) validation of the assumption that equal bit ratios are preferable; (iv) optimization benefits such as search-space reduction and good minima; (v) favorable results compared to the state-of-the-art, and can ensure half-half weight distribution even when pruning is used.

2 Related Work

For a comprehensive survey on binary networks, see (Qin et al. 2020a). In Table 1 we show the relation between our proposed method and pioneering methods, that are representatives of their peers, in terms of the binarization choices made. The XNOR method (Table 1(a)) was the first to propose binarizing latent real-valued weights using the sign function (Rastegari et al. 2016). Rather than making each binary weight depend only on its associated real-value weight or gradient value, IR-Net (Qin et al. 2020b) (Table 1(b)) is a prototype method that uses filter-weight statistics to update each individual binary weight. Here, we also use filter-weight statistics to update the binary weights, however similar to (Helwegen et al. 2019) Table 1(d) we do not rely on the sign function for binarization, but instead use binary weight flips. This is a natural choice, as flipping the sign of a binary weight is the only operation one can apply to binary weights.

Sign versus bit flips. The front-runners of binary networks are BinaryConnect (Courbariaux, Bengio, and David 2015) and XNOR (Rastegari et al. 2016) and rely on auxiliary real weights and the sign function to define binary weights.

Gradient (Helwegen et al. 2019) Gradient
Our predefined threshold selected important weights are typically not useful for the re-winded (Frankle and Carbin 2020) from a large trained weight values are inherited (Han, Mao, and Dally 2016) or can bring improvements remains unclear in real-valued networks. However, the reason why pruning works (Helwegen et al. 2019; Ye et al. 2020). However, the reason why pruning can bring improvements remains unclear in real-valued networks. It is commonly believed (Evci et al. 2020; Frankle and Carbin 2020; Malach et al. 2020; Zhou et al. 2019) that finding the “important” weight values is crucial for retraining a small pruned model. Specifically, the “important” weight values are inherited (Han, Mao, and Dally 2016) or re-winded (Frankle and Carbin 2020) from a large trained model. In contrast, (Liu et al. 2019) claims that the selected important weights are typically not useful for the small pruned model, while the pruned architecture itself is more relevant. The lottery-ticket idea has recently been applied to binary networks (Diffenderfer and Kailkhura 2021). Here, we show that having equal +1 and −1 ratios is also optimal when the networks rely on pruning and that our optimal transport optimization can easily be adapted to work with methods using pruning.

3 Binarizing with optimal transport

3.1 Binary weights

We define a binary network where the weights B take binary values {1, −1}^D. The binary weights B follow a Bernoulli distribution B ∼ Be(ppos), describing the probabilities of individual binary values b ∈ {−1, 1} in terms of the hyper-parameters ppos and pneq:

\[ p(b) = \text{Be}(b \mid p_{pos}) = \begin{cases} p_{pos} & \text{if } b = +1 \\ 1 - p_{pos} & \text{if } b = -1 \end{cases} \]

To be consistent with previous work, we follow XNOR-Net (Rastegari et al. 2016) and apply the binary optimization per individual filter.

Because the matrix B is discrete, we follow (Courbariaux, Bengio, and David 2015; Rastegari et al. 2016) by using real-valued latent weights W to aid the training of discrete values, where each binary weight in B has an associated real-valued weight in W. In the forward pass we quantize the real-valued weights W to estimate the matrix B. Then, we use the estimated matrix B to compute the loss, and in the backward pass we update the associated real-valued weights W.

3.2 Optimal transport optimization

The optimization aligns the real-valued weight distribution W with the prior Bernoulli distribution given by Eq. (1) and quantizes the real-valued weights W to B.

The empirical distribution P_w of the real-valued variable W ∈ R^D and the empirical distribution P_b for the discrete variable B can be written as:

\[ P_w = \sum_{i=1}^{D} p_i \delta_{w_i}, \quad P_b = \sum_{j=1}^{2} q_j \delta_{b_j}, \]

Table 1: Optimization perspectives. (a) Classical binarization methods tie each binary weight b to an associated real-valued latent variable w, and quantize each weight by only considering its associated real-valued by using the sign function. (b) Rather than updating the weights independent of each other, recent work uses filter-statistics when updating the binary weights. (c) Our proposed optimization method does not focus on using the sign function, but rather flips the binary weights based on the distribution of the real weights, thus the binary weight updates depend on the statistics of the other weights through the range of w. (d) Recent work moves away from using the sign of the latent variables, and instead trains the binary network with bit-sign flips, however they still consider independent weight updates.
where $\delta_x$ is the Dirac function at location $x$. The $p_i$ and $q_j$ are the probability mass associated to the corresponding distribution locations $w_i$ and $b_j$, where $P_w$ has only 2 possible locations in the distribution space $\{-1, 1\}$.

To align $P_w$ with the Bernoulli prior $P_b$ in Eq. (1) we use optimal transport (OT) [Villani 2003] which minimizes the cost of moving the starting distribution $P_w$ to the target distribution $P_b$. Because $P_w$ and $P_b$ are only accessible through a finite set of values, the corresponding optimal transport cost is:

$$\pi_0 = \min_{\pi \in \Pi(P_w, P_b)} \langle \pi, C \rangle_F,$$

where $\Pi(P_w, P_b)$ is the space of the joint probability with marginals $P_w$ and $P_b$, and $\pi$ is the general probabilistic coupling that indicates how much mass is transported to push distribution $P_w$ towards the distribution $P_b$. The $\langle \cdot, \cdot \rangle_F$ denotes the Frobenius dot product, and $C \geq 0$ is the cost function matrix whose element $C(w_i, b_j)$ denotes the cost of moving a probability mass from location $w_i$ to location $b_j$ in distribution space. When the cost is defined as a distance, the OT becomes the Wasserstein distance. We minimize the 1-Wasserstein distance between $P_w$ and $P_b$. This minimization has an elegant closed-form solution based on simply sorting. For a continuous-valued weights vector $W \in \mathbb{R}^D$, we first sort the elements of $W$, and then assign the top $p_{pos}D$ elements to +1, and the bottom $(1 - p_{pos})D$ portion of the elements to −1:

$$B = \pi_0(W) = \begin{cases} +1, & \text{top } p_{pos}D \text{ of sorted } W \\ -1, & \text{bottom } (1 - p_{pos})D \text{ of sorted } W \end{cases}$$

(4)

Rather than using the sign function to define the binarization, we flip the binary weights based on the distribution of $W$. Thus the flipping of a binary weight depends on the distribution of the other binary weights through $W$, which is optimized to be as close as possible to $B$.

When applying our method in combination with pruning as in [Diffenderfer and Kaikhurst 2021], we first mask the binary weights $B^* = M \odot B$ with a mask $M \in \{0, 1\}^P$. This leads to a certain percentage of the weights being pruned. Subsequently, we apply the Eq. (4) to the remaining non-pruned weights, where $D$ in Eq. (4) become the $L_1$ norm of the mask, $|M|$.

### 3.3 Bi-half: Explicitly controlling the bit ratio

Our optimal transport optimization allows us to enforce a hard constraint on precise bit ratios by varying the $p_{pos}$ value. Therefore, we can test a range of prior binary weight distributions.

Following [Qin et al. 2020b], a good prior over the binary weights is one maximizing the entropy. Using optimal transport, we maximize the entropy of the binary weights by setting the bit ratio to half in Eq. (4):

$$p_{pos}^* = \arg\max_{p_{pos}} H(p_{pos}B \sim \text{Be}(p_{pos})) = \frac{1}{2},$$

(5)

where $H(\cdot)$ denotes the entropy of the binary weights $B$. We dub this approach bi-half. Unlike previous work [Qin et al. 2020b], we can guarantee equal symbol distributions and therefore maximum entropy throughout the complete training procedure.

### Initialization and scaling factor

We initialize the real-valued weights using Kaiming normal [He et al. 2015]. The binary weights are initialized to be equally distributed per filter according to Eq. (5). To circumvent exploding gradients, we use one scaling factor $\alpha$ per layer for the binary weights to keep the activation variance in the forward pass close to 1. Based on the ReLU variance analysis in [He et al. 2015] it holds that $\frac{1}{2}D \cdot \text{Var}(\alpha B) = 1$, where $D$ is the number of connections and $B$ are our binary weights. $\alpha$ is regularized to a bi-half distribution, thus $\text{Var}(B) = 1$, which gives $\alpha = \sqrt{2/D}$.

To better clarify, for an $L$-layer network with input data $y_1$ standardized to $\text{Var}(y_1) = 1$, where the variance of each binary layer $l$ is $\text{Var}(B_l) = 1$, and $D_l$ is the number of connections in that layer: i) Without the scaling, the output variance is $\text{Var}(y_L) = \text{Var}(y_1) \prod_{l=2}^{L} \frac{D_l}{D} \text{Var}(B_{l}) = \prod_{l=2}^{L} \frac{D_l}{D}$. Typically $D_l$ is large, leading to exploding gradients; ii) With the scaling, we scale $B_l$ by $\alpha = \sqrt{2/D_l}$, leading to $\text{Var}(y_L) = \text{Var}(y_1) \prod_{l=2}^{L} \frac{D_l}{D} \text{Var}(\alpha B_{l}) = 1$ which stabilizes learning.

### 4 Experiments

**Datasets and implementation details.** We evaluate on Cifar-10, Cifar-100 [Krizhevsky, Hinton et al. 2009] and ImageNet [Deng et al. 2009], for a number of network architectures. Following [Frankle and Carbin 2020; Ramanujan et al. 2020] we evaluate 4 shallow CNNs: Conv2, Conv4, Conv6, and Conv8 with 2/4/6/8 convolutional layers. We train the shallow models on Cifar-10 for 100 epochs, with weight decay $1e^{-4}$, momentum 0.9, batch size 128, and initial learning rate 0.1 using a cosine learning rate decay [Loshchilov and Hutter 2016]. Following [Qin et al. 2020b] we also evaluate their ResNet-20 architecture and settings on Cifar-10. On Cifar-100, we evaluate our method on 5 different models including VGG16 [Simonyan and Zisserman 2015], ResNet18 [He et al. 2016], ResNet34 [He et al. 2016], InceptionV3 [Szegedy et al. 2016], ShuffleNet [Zhang et al. 2018]. We train the Cifar-100 models for 350 epochs using SGD with weight decay $5e^{-4}$, momentum 0.9, batch size 128, and initial learning rate 0.1 divided by 10 at epochs 150, 250 and 320. For ImageNet we use ResNet18 and ResNet34 trained for 100 epochs using SGD with momentum 0.9, weight decay $1e^{-4}$, and batch size 256. Following [Liu et al. 2018; Qin et al. 2020b], the initial learning rate is set as 0.1 and we divide it by 10 at epochs 30, 60, 90. All our models are trained from scratch without any pre-training. For the shallow networks we apply our method on all layers, while for the rest we follow [Liu et al. 2018; Qin et al. 2020b], and apply it on all convolutional and fully-connected layers except the first, last and the downsampling layers.

### 4.1 Hypothesis: Bi-half maximizes the entropy

Here we test whether our proposed bi-half model can indeed guarantee maximum entropy and therefore an exactly equal ratio of the $-1$ and $+1$ symbols. Fig. 2 shows the
Figure 1: **Hypothesis: bi-half maximizes the entropy.** Entropy of binary weights and activations. We compare our bi-half method to sign (Rastegari et al. 2016) and IR-Net (Qin et al. 2020b). (a) Entropy of the binary weights during training for Conv2 on Cifar10. (b) Entropy of the network activations for ResNet-18 on Cifar100. Our bi-half model can guarantee maximum entropy during training for the binary weight distribution and it is able to better maximize the entropy of the activations.

Figure 2: **Hypothesis: bi-half maximizes the entropy.** Bit flips during training. We compare the bit flips during training in our bi-half with the sign (Rastegari et al. 2016) and IR-Net (Qin et al. 2020b) on the Conv2 network on Cifar-10. The x-axis shows the training iterations. Left: Bit flips during training to +1 (dark blue) or to -1 (cyan). Right: Accumulated bit flips over the training iterations, as well as the difference between the bit flips from (+1 to -1) and the ones from (-1 to +1). In contrast to sign and IR-Net, our bi-half method can guarantee an equal bit ratio.

4.2 Empirical analysis

(a) Effect of hyper-parameters. In Fig. 3 we study the effectiveness of the commonly used training techniques of varying the weight decay and learning rate decay, when training the Conv2 network on Cifar-10. Fig. 3(a) shows that using a higher weight decay reduces the magnitude of latent weights during training and therefore the magnitude of the cut-off point (threshold) between the positive and negative values. Fig. 3(b) compares the gradient magnitude of
Figure 3: Empirical analysis (a): Effect of hyper-parameters. We show the effect of weight decay and learning rate decay on binary weights flips using the Conv2 network on Cifar-10. Carefully tuning these hyper-parameters is important for adequately training the binary networks.

Figure 4: Empirical analysis (c): Optimization benefits. We train our bi-half model 100 times on Cifar-10 and plot the distribution of the losses and accuracies over the 100 repetitions. We compare our results using optimal transport to the results using the standard sign function. On average our bi-half model tends to arrive at better losses and accuracies than the baseline.

Figure 5: Empirical analysis (b): Which bit-ratios are preferred? We vary the bit-ratios on Cifar-10 and Cifar-100 using Conv2 the choice of the prior $p_{pos}$ under the Bernoulli distribution. The x-axis is the probability of the +1 connections denoted by $p_{pos}$ in the Bernoulli prior distribution, while the y-axis denotes the top-1 accuracy values. Results are in agreement with the hypothesis of Qin et al. (Qin et al. 2020b) that equal priors as imposed in our bi-half model are preferable.

Therefore in the experiments, we carefully tune the hyper-parameters of weight decay and learning rate decay to build a competitive baseline.

(b) Which bit-ratio is preferred? In Fig. 5 we evaluate the choice of the prior $p_{pos}$ in the Bernoulli distribution for Conv2 on Cifar-10 and Cifar-100. By varying the bit-ratio, the best performance is consistently obtained when the negative and positive symbols have equal priors as in the bi-half model. Indeed, as suggested in (Qin et al. 2020b), when there is no other a-priori reason to select a different $p_{pos}$, having equal bit ratios is a good choice.

(c) Optimization benefits with bi-half. The uniform prior over the $-1$ and $+1$ under the Bernoulli distribution regularizes the problem space, leading to only a subset of possible weight combinations available during optimization. We illustrate this intuitively on a 2D example for a simple fully-connected neural network with one input layer, one hidden layer, and one output layer in a two-class classification setting. We consider a 2D binary input vector $x = [x_1, x_2]^T$, and define the network as: $\sigma(w_2^T \sigma(w_1^T x + b_1))$, where $\sigma(\cdot)$ is a sigmoid nonlinearity, $w_1$ is a $2 \times 3$ binary weight matrix, $b_1$ is a $[3 \times 1]$ binary bias vector, and $w_2$ is a $[3 \times 1]$ binary vector. We group all 12 parameters as a vector $B$. We enumerate all possible binary weight combinations in $B$, i.e. $2^{12} = 4096$, and plot all decision boundaries that separate the input space into two classes as shown in Fig. 6(a). All possible 4096 binary weights combinations offer only 76 unique decision boundaries. In Fig. 6(b) the Bernoulli distribution over the weights with equal prior (bi-half) regularizes the problem space: it reduces the weight combinations to 924, while retaining 66 unique solutions, therefore
On average, the bi-half uses of the losses for our test accuracy. To better visualize this trend we sort the values with lower training and test losses and higher training and accuracies. We plot these results when using the bi-half and accuracies. We plot these results when using the bi-half optimization with optimal transport and by training the network using the standard sign function. The figure shows the bi-half regularization: 2D example for a 12-parameter fully connected binary network \( \sigma(w_2 \cdot \sigma(w_1^T x + b_1)) \), where \( \sigma(\cdot) \) is a sigmoid nonlinearity. Weights are in \([-1, 1]\). (a) Enumeration of all decision boundaries for 12 binary parameters (4096 = \(2^{12}\) combinations). (b) Weight combinations and unique solutions when using our bi-half constraint. (c) The weight combinations and unique decision boundaries for various bit-ratios. When the number of negative binary weights is 6 on the x-axis, we have equal bit-ratios, which is the optimal ratio. Using the bi-half works as a regularization, reducing the search-space while retaining the majority of the solutions.

Figure 6: **Empirical analysis (c): Optimization benefits.** Bi-half regularization: 2D example for a 12-parameter fully connected binary network \( \sigma(w_2 \cdot \sigma(w_1^T x + b_1)) \), where \( \sigma(\cdot) \) is a sigmoid nonlinearity. Weights are in \([-1, 1]\). (a) Enumeration of all decision boundaries for 12 binary parameters (4096 = \(2^{12}\) combinations). (b) Weight combinations and unique solutions when using our bi-half constraint. (c) The weight combinations and unique decision boundaries for various bit-ratios. When the number of negative binary weights is 6 on the x-axis, we have equal bit-ratios, which is the optimal ratio. Using the bi-half works as a regularization, reducing the search-space while retaining the majority of the solutions.

Figure 7: **Architecture variations: Different architectures on Cifar-100.** We evaluate on Cifar-100 over 5 different architectures: VGG16 (Simonyan and Zisserman 2015), ResNet18 (He et al. 2016), ResNet34 (He et al. 2016), InceptionV3 (Szegedy et al. 2016), ShuffleNet (Zhang et al. 2018). We compare sign (Rastegari et al. 2016), IR-Net (Qin et al. 2020b) and our bi-half. The 1/32 and 1/1 indicate the bit-width for weights and for activations, where 1/1 means we quantize both the weights and the activations to binary code values. Our method achieves competitive accuracy across different network architectures.

In Table 2, we compare the Sign (Rastegari et al. 2016), IR-Net (Qin et al. 2020b) and our bi-half on four shallow Conv2/4/6/8 networks on Cifar-10 (averaged over 5 trials). As the networks become deeper, the proposed bi-half method consistently outperforms the other methods.

In Fig. 7, we further evaluate our method on Cifar-100 over 5 different architectures: VGG16 (Simonyan and Zisserman 2015), ResNet18 (He et al. 2016), ResNet34 (He et al. 2016), InceptionV3 (Szegedy et al. 2016), ShuffleNet (Zhang et al. 2018). Our method is slightly more accurate than the other methods, especially on the VGG16 architecture, it never performs worse.

4.3 **Architecture variations**

In Table 2 we compare the Sign (Rastegari et al. 2016), IR-Net (Qin et al. 2020b) and our bi-half on four shallow Conv2/4/6/8 networks on Cifar-10 (averaged over 5 trials). As the networks become deeper, the proposed bi-half method consistently outperforms the other methods.

In Fig. 7 we further evaluate our method on Cifar-100 over 5 different architectures: VGG16 (Simonyan and Zisserman 2015), ResNet18 (He et al. 2016), ResNet34 (He et al. 2016), InceptionV3 (Szegedy et al. 2016), ShuffleNet (Zhang et al. 2018). Our method is slightly more accurate than the other methods, especially on the VGG16 architecture, it never performs worse.

4.4 **Comparison with state-of-the-art**

(a) **Comparison on ImageNet.** For the large-scale ImageNet dataset we evaluate a ResNet-18 and ResNet-34 backbone (He et al. 2016). Table 3 shows a number of negative binary weights vs bit-ratios.
(b) Comparison on pruned networks. In Fig. 8, we show the effect of our bi-half on pruned models. Following the MPT method [Diffenderfer and Kailkhura 2021], we learn a mask for the binary weights to prune them. However, in our bi-half approach for pruning, we optimize using optimal transport for equal bit ratios in the remaining unpruned weights. We train shallow Conv2/4/6/8 networks on CIFAR-10, and ResNet-18 on CIFAR-100 while varying the percentage of pruned weights. Each curve is the average over five trials. Pruning consistently finds subnetworks that outperform the full binary network. Our bi-half method with optimal transport retains the information entropy for the pruned subnetworks, and consistently outperforms the MPT baseline using the sign function for binarization.

5 Conclusion

We focus on binary networks for their well-recognized efficiency and memory benefits. To that end, we propose a novel method that optimizes the weight binarization by aligning a real-valued proxy weight distributions with an idealized distribution using optimal transport. This optimization allows to test which prior bit ratio is preferred in a binary network, and we show that the equal bit ratios, as advertised by Qin et al. 2020b, indeed work better. We confirm that our optimal transport binarization has optimization benefits such as: reducing the search space and leading to better local optima. Finally, we demonstrate competitive performance when compared to state-of-the-art, and improved accuracy on 3 different datasets and various architectures. We additionally show accuracy gains with pruning techniques.

Table 3: Comparison with state-of-the-art (a): ImageNet results. We show Top-1 and Top-5 accuracy on ImageNet for a number of state-of-the-art binary networks. Sign is our baseline by carefully tuning the hyper-parameters. Our proposes bi-half model consistently outperforms the other binarization methods on this large-scale classification task.

Table 2: Architecture variations. Accuracy comparison of sign ([Rastegari et al. 2016], IR-Net [Qin et al. 2020b]) and our bi-half on Conv2/4/6/8 networks using Cifar-10, over 5 repetitions. As the depth of the network increases, the accuracy of our method increases.

Table 4: Percent of Pruned Weights.

Figure 8: Comparison with state-of-the-art (b): Pruned networks. Test accuracy of Conv2/4/6/8 on CIFAR-10, and ResNet-18 on CIFAR-100 when varying the % pruned weights. We compare with the MPT baseline [Diffenderfer and Kailkhura 2021] using binary weight masking and the sign function. Having equal +1 and −1 ratios is also optimal when the networks rely on pruning and that our optimal transport optimization can easily be adapted to work in combination with pruning.

| bi-half (ours) | 1/1 | **64.17** | **85.36** |

ResNet-34

| Backbone | Method      | Bit-width | Top-1(%) | Top-5(%) |
|----------|-------------|-----------|----------|----------|
| FP       | 32/32       | 69.3      | 89.2     |
| ABC-Net  | 1/1         | 42.7      | 67.6     |
| XNOR     | 1/1         | 51.2      | 73.2     |
| BNN+     | 1/1         | 53.0      | 72.6     |
| Least-squares | 1/1   | 58.9      | 81.4     |
| XNOR++   | 1/1         | 57.1      | 79.9     |
| IR-Net   | 1/1         | 58.1      | 80.0     |
| RBNN     | 1/1         | 59.9      | 81.9     |
| Sign (Baseline) | 1/1  | 59.98     | 82.47    |
| Bi-half (ours) | 1/1 | **60.40** | **82.86** |

Table 3: Comparison with state-of-the-art (a): ImageNet results. We show Top-1 and Top-5 accuracy on ImageNet for a number of state-of-the-art binary networks. Sign is our baseline by carefully tuning the hyper-parameters. Our proposes bi-half model consistently outperforms the other binarization methods on this large-scale classification task.

Table 4: Comparison with state-of-the-art (b): Pruned networks. Test accuracy of Conv2/4/6/8 on CIFAR-10, and ResNet-18 on CIFAR-100 when varying the % pruned weights. We compare with the MPT baseline [Diffenderfer and Kailkhura 2021] using binary weight masking and the sign function. Having equal +1 and −1 ratios is also optimal when the networks rely on pruning and that our optimal transport optimization can easily be adapted to work in combination with pruning.
