Abstract: Three recurring hypotheses are often used to explain the effect of non-thermal plasmas (NTPs) on NTP catalytic hybrid reactions; namely, modification or heating of the catalyst or creation of new reaction pathways by plasma-produced species. NTP-assisted methane (CH₄) oxidation over Pd/Al₂O₃ was investigated by direct monitoring of the X-ray absorption fine structure of the catalyst, coupled with end-of-pipe mass spectrometry. This in situ study revealed that the catalyst did not undergo any significant structural changes under NTP conditions. However, the NTP did lead to an increase in the temperature of the Pd nanoparticles; although this temperature rise was insufficient to activate the thermal CH₄ oxidation reaction. The contribution of a lower activation barrier alternative reaction pathway involving the formation of CH₃(g) from electron impact reactions is proposed.

Methane is a major contributor to climate change, with a global warming potential at least 21 times higher than that of CO₂; consequently, its release into the atmosphere must be stringently controlled. In addition to controlling CH₄ release from landfills, biomass burning, and leakage from natural gas storage and distribution, emission abatement arising from CH₄ slip in automotive vehicles must also be addressed.

One solution is to use catalytic total oxidation to produce CO₂ and water. Palladium is a known efficient catalyst for CH₄ oxidation and has been studied extensively. Varying hypotheses of the active phase have been reported, from a PdO-like phase to Pd⁴⁺[1] Unfortunately, of all the catalysts currently reported, none are sufficiently active under cold-start conditions, with most catalysts requiring light-off temperatures of around 400°C.[2] Such high temperatures are required because of the high activation barriers to CH₄ dehydrogenation; particularly formation of surface adsorbed CH₃⁺ and H⁺, which is thought to be the rate-determining step. For example, Jørgensen and Grønbeck predicted that the extraction of the first H from CH₃ had activation barriers of 0.99 and 0.79 eV over Pd(111) and Pd(100), respectively.[3]

One known method for inducing catalytic activity in kinetically restricted reactions at low temperatures is by coupling non-thermal plasmas (NTPs) with catalysis. Recent examples are the selective catalytic reduction of NOₓ, volatile organic carbon (VOC) removal, and water gas shift without the need for an external heating source. Similarly, NTP-assisted CH₄ oxidation has been reported at low temperature, where no additional heat source is applied, and at elevated temperatures, where the catalyst is also heated to temperatures up to 300°C.[4]

Three recurring hypotheses are often proposed to explain the assistance which NTP gives to catalytic reactions: 1) the plasma modifies the catalyst, 2) the plasma heats the catalyst, and 3) the assistance of the plasma permits occurrence of new reaction pathways. NTP has been shown, in some cases, to alter the catalysts itself by changing the oxidation state[5] or metal surface area[6,7] of the components. Several attempts...
have been made to determine the temperature of a catalyst during NTP reactions, using thermocouples placed near or in the catalyst bed, or by observation with infrared cameras or optical emission spectroscopy.[8] However, no study has yet directly measured the temperature of the metal nanoparticles within the catalyst and compared this with the overall bed temperature during a NTP-assisted catalytic reaction. The interaction of radicals, electrons, or photons produced by the NTP with the catalyst and the adsorbed molecules may open up new reaction pathways. For instance, the direct reaction of gas-phase radicals with adsorbed species (that is, a direct Eley–Rideal mechanism) could occur.[9] Desorption from the catalyst surface may also be aided by electron impact.[10] To investigate which of these hypotheses are operating under NTP-assisted catalysis, in situ investigations are crucial. Very few in situ plasma catalytic studies have been performed.[11] One recent example involved investigation of the hydrocarbon selective catalytic reduction (HC-SCR) of NOx over Ag/Al2O3.[12] This investigation used a modified diffuse reflectance infrared Fourier transform (DRIFTS) setup to follow the adsorbates during the thermal and the NTP-enhanced reactions; providing invaluable information on adsorbed species and the mechanism of the reaction. However, to the best of our knowledge, no in situ structural studies have been undertaken to characterize the catalyst during NTP-assisted reactions. In the study reported herein, we have probed NTP-assisted CH4 oxidation, in the absence of any applied external heating, using in situ X-ray absorption fine structure (XAFS) information. The results provide significant new insights into the role of plasma-induced heating effects in the NTP-assisted process.

The NTP-activated oxidation of CH4 over a 2% Pd/Al2O3 (sample 1; Supporting Information, Table S1) was examined at applied voltages of 6 and 7 kV at 22.5 kHz. In the absence of an externally applied heating source, 55% (6 kV) and 67% (7 kV) CH4 conversions were observed. In the presence of the catalyst, high selectivities were found (CO:CO2 1:10.8 (6 kV) and 1:11.5 (7 kV)) and negligible amounts of H2 were formed. Additionally, a temperature-programmed oxidation measurement of the catalyst following CH4 oxidation showed little carbon deposition with no significant oxidation above > 600°C (Supporting Information, Figure S1). Notably, in the absence of the catalyst, the conversion was similar (68% at 7 kV), significantly more CO was formed (CO:CO2 1:1.1). These results may also be compared with the reaction over the discrete support in the presence of the plasma, which had a reduced conversion of 59% and a CO:CO2 ratio of 1.2:1.1. These observations demonstrate the importance of the catalyst in determining the selectivity of the reaction. The specific energy input (SEI) calculated for the 6 and 7 kV plasma in the presence of the catalyst was 2.133 kJ L−1 and 2.637 kJ L−1, respectively.

Similar conversions/selectivities were also obtained during the X-ray absorption spectroscopy (XAS) investigation monitored by end-of-pipe mass spectrometry (MS) analysis (sample 1, 52% conversion at 6 kV; Supporting Information, Figure S2). The setup, shown in Figure 1 and Figure S3 (Supporting Information), allowed XAFS measurements along the length of the packed catalyst bed to be monitored. XAFS measurements were performed at the Pd K-edge on the B18 beamline at the Diamond Light Source, United Kingdom.

The X-ray absorption near-edge structure (XANES) of the fresh catalyst (sample 1) under thermal CH4 oxidation reaction (352°C) compared to that under CH4 oxidation using the plasma are very similar, as shown in Figure 2. On first inspection, there is little impact of the plasma on the catalyst, with the spectra closely resembling that of PdO. When oxygen is removed from the system under plasma, leaving just 5000 ppm CH4 and He balance, the catalyst is reduced, as shown by a shift in the edge position of 2 eV, and the spectra are very similar to that of the Pd foil reference. Analysis of the extended X-ray absorption fine structure (EXAFS) region reveals only very subtle differences in the spectra when comparing the plasma-activated and thermally activated catalysts under CH4 oxidation conditions. Spectra collected at two positions, 2.5 and 7.5 mm from the start of the catalyst bed, are shown in Figure 3 and the fitting parameters are shown in Table 1. In both cases the oscillations are dampened.
when the plasma is on compared to when it is off. No other differences are observed in the spectra; for example no shift in phase or additional features are observed that would indicate changes in distance to nearest neighbors or changes in the coordination around the absorber atom. Furthermore, on turning off the plasma, no change was found compared with the fresh catalyst (Supporting Information, Figure S4), demonstrating the reversibility of the changes and indicating that no significant permanent changes to the nanoparticle structure had occurred. Notably, XAFS is a bulk-averaging technique; therefore, we cannot exclude that some minor non-reversible changes to the Pd nanoparticles may occur, which are below the detection level of the technique. However, the EXAFS results are consistent with transmission electron micrographs (TEM) of the catalyst before and after the plasma treatment, which showed similar particle sizes 2.1 ± 1.0 and 2.9 ± 1.4 nm and no change in the shape of the nanoparticles observed (Supporting Information, Figure S5). We propose that the subtle dampening of the oscillations is due to an increase in the temperature of the Pd under the application of the plasma, when an increase in the mean-squared thermal disorder parameter ($\sigma^2$) corresponds to a decrease in the amplitude of the EXAFS oscillations. Similarly, weak oscillations were also observed for a range of catalyst loadings and particle sizes (samples 1–4; Supporting Information, Table S1) under plasma conditions. As no other measurable changes occur to the catalyst, the change in $\sigma^2$ can be used to estimate the temperature of the Pd nanoparticles on the catalyst. A data set was obtained on cooling of the catalyst from 500 °C to room temperature under air, which indicated no structural changes on cooling and was used to determine a calibration curve of the variation of $\sigma^2$ with temperature.

The calibration curve and fitting parameters are shown in the Supporting Information, Figures S6–S9 and Tables S2 and S3. These data were then used to determine the temperature of the catalysts when activated by the plasma. To fit the data upon cooling, the EXAFS fit was performed, allowing the coordination numbers (CN), $\sigma^2$ values, and distances to refine. The determined CN values were then fixed when fitting the plasma-activated spectrum, allowing only $\sigma^2$ and distances to refine. This value was then used to estimate the temperature of the catalyst when activated by the plasma (Supporting Information, Table S4). For all the catalysts studied the estimated temperatures ranged from 138 to 179 °C in the middle of the bed. Additionally, measurements were made for sample 1 comparing the front and middle of the bed, and the temperatures were determined to be 203 ± 32 and 152 ± 28 °C, respectively. The fitting parameters (Table 1) and the data and fit are shown in Figure S7 (Supporting Information). The higher temperature at the front of the bed is expected as the CH$_4$ oxidation is exothermic and the rate will be highest towards the start of the catalyst bed. Using Aspen software (Aspen Technology), a simulation of the reaction using the same reactant concentrations and assuming thermodynamic equilibrium (that is, full CH$_4$ conversion) provided a reactor temperature of approximately 210 °C, which is consistent with the exothermicity of the CH$_4$ oxidation.

The estimated temperatures of the catalyst bed were significantly higher than those measured using an infrared (IR) camera, Figure 4 (60–90 °C), which is a technique commonly used to determine plasma reaction temperatures.

Table 1: EXAFS Fitting Parameters for Pd K-Edge spectra taken under CH$_4$ oxidation and CH$_4$-only conditions for sample 1.

| Conditions                  | Absorber–Scatterer | $\Delta E$ [eV] | CN$^1$ | $R_{el}$ [Å] | $\sigma^2$ | $\sigma^2$ | $T$ [°C] |
|-----------------------------|----------------------|-----------------|--------|-------------|------------|------------|----------|
|                            |                      |                 |        |             | (plasma ON) | (plasma ON) |          |

[a] Fitting parameters: $S_2^2 = 0.83$, as determined by the use of a Pd foil standard. Fit range 3.0 < $k$ < 16.0, 1.0 < $R$ < 3.5; number of independent points $= 20.5$. [b] Fitting parameters: $1.2 < R < 4$, $3.4 < k < 10.6$; number of independent points $= 12.6$. 

Figure 3. $k^2 \chi(k)$ data for CH$_4$ oxidation at the start (position 2.5) and middle (position 7.5) of the catalyst (sample 1) bed, under plasma ON and plasma OFF conditions, and the CH$_4$-only experiment under plasma ON and OFF conditions.
This measurement is not surprising as the IR camera predominantly measures the outside wall of the reactor and will significantly underestimate the temperature within the packed bed.

To determine if the observed heating of the catalyst was because of the exothermicity of the CH$_4$ oxidation reaction or induced by the plasma, the reaction was performed in the absence of O$_2$. Under these conditions the reaction of CH$_4$ is endothermic and results in coupling products.$^{[13]}$ During the endothermic non-oxidative CH$_4$ coupling, the EXAFS data (Figure 2, Table 1) obtained when the plasma is both on and off resembles that of the Pd foil; therefore, the PdO catalyst has been, unsurprisingly, reduced on removal of oxygen from the feed gas. Using the value of $\alpha^2$ calculated from this data, the estimated temperature during the plasma was 207 ± 32°C (Table 1). From these results we conclude that the plasma is responsible for the observed heating effect.

The fact that there are no significant nanoparticle size- or catalyst loading-dependent changes on the temperatures calculated from the XAFS may suggest that the surface of the whole catalyst (nanoparticle and oxide) is being heated. The XAFS data only probes the Pd, which, however, does not preclude the alumina surface from also being heated. In this case, the support and nanoparticle would be in thermal equilibrium, thereby leading to similar changes in temperature for all the catalysts studied.

Taking account of all the data acquired, the estimated temperature of the nanoparticles during NTP-activated CH$_4$ oxidation is 162 ± 24°C, which is within the error of the calculated temperature from the exothermicity of the CH$_4$ oxidation reaction. Therefore, a clear difference in temperature is observed between the EXAFS estimation and that measured by the IR camera. Almost a two-fold increase in temperature of the nanoparticles is measured compared to the overall temperature of the catalyst bed. However, this temperature (162°C) is not high enough to activate the thermal CH$_4$ oxidation reaction. Therefore, it is likely that an alternative CH$_4$ activation pathway is in operation, with a lower activation barrier for CH$_4$ dehydrogenation.
