Statistical averaging theorems allow us to derive a set of equations for the averaged magnetization dynamics in the presence of colored (non-Markovian) noise. The non-Markovian character of the noise is described by a finite auto-correlation time, \( \tau \), that can be identified with the finite response time of the thermal bath to the system of interest. Hitherto, this model was only tested for the case of weakly correlated noise (when \( \tau \) is equivalent or smaller than the integration timestep). In order to probe its validity for a broader range of auto-correlation times, a non-Markovian integration model, based on the stochastic Landau-Lifshitz-Gilbert equation is presented. Comparisons between the two models are discussed, and these provide evidence that both formalisms remain equivalent, even for strongly correlated noise (i.e. \( \tau \) much larger than the integration timestep).

Index Terms—Stochastic magnetization dynamics, Non-Markovian effects, Multiscale models.

I. INTRODUCTION

The study of the effects of thermal fluctuations on the magnetization dynamics, by way of stochastic simulations, is a topic that has received much attention \([1], [2]\). What has also been the subject of numerous studies, in the field of coarse-grained simulations \([3]\), is the development of multiscale models, able to simulate the average magnetic behaviour of a spin assembly under thermal stresses \([4], [5]\). But in both contexts, the coupling between the thermal bath and the spin assembly has mainly been taken into account within the framework of the white-noise limit, and few studies \([6], [7]\) have considered the effects of a finite auto-correlation time for the response of the thermal bath, i.e. the case of colored noise.

However, the simulation of ultra-fast magnetic experiments \([8], [9]\) is now able to probe time-scales of the dynamics of comparable order of magnitude \([10], [11]\) to the auto-correlation time of the external random field. In these situations, a colored form for the noise, introducing a finite auto-correlation time, can provide a better description for the random variables of the bath \([6], [7]\).

The bath variables can be defined by random vectors \( \tilde{\omega} \) whose components \( \tilde{\omega}_i \) are drawn from a Gaussian distribution with zero mean and second-order autocorrelation functions:

\[
\langle \tilde{\omega}_i(t)\tilde{\omega}_j(t') \rangle = \frac{D}{\tau} \delta_{ij} \exp\left(-\frac{|t-t'|}{\tau}\right)
\]

(1)

with \( \tau \) the auto-correlation time, \( D \) the amplitude of the noise. Wick’s theorem allows us to express all other autocorrelation functions in terms of these one- and two-point functions \([12]\).

When the auto-correlation time vanishes (\( \tau \rightarrow 0 \)), the well-known white-noise limit is recovered: \( \langle \tilde{\omega}_i(t)\tilde{\omega}_j(t') \rangle = 2D\delta_{ij}\delta(t-t') \).

\[\text{Corresponding author: J. Tranchida (email: julien.tranchida@cea.fr).}\]

In previous work \([13]\), statistical averaging theorems \([14]\) were applied to a non-Markovian form of the stochastic Landau-Lifshitz-Gilbert equation (sLLG), and they allowed us to derive a new hierarchy of equations for the simulation of averaged magnetization dynamics. Under Gaussian assumptions, the hierarchy of equations was closed, and a new model, presenting both transverse and longitudinal forms of damping, was obtained. This model is denoted as the dynamical Landau-Lifshitz-Bloch model (dLLB). A first benchmark of tests was performed, and the validity of our closure assumptions was checked to hold for weakly correlated noise (i.e. \( \tau \rightarrow 0 \)), and with a constant applied magnetic field. However, the case of strongly correlated noise was left for future investigations—in the present paper we discuss our first results along this path.

In section II, the non-Markovian sLLG model is presented, and compared with other works based on non-Markovian stochastic magnetization dynamics. Then, some numerical experiments are presented in order to assess some aspects of this model, and to probe the impact of the auto-correlation time \( \tau \) on the magnetization dynamics.

Section III introduces our dLLB model. The results of numerical experiments, performed to assess the range of validity of our closure assumptions, for different domains of values of \( \tau \), i.e. beyond Markovian situations are discussed.

We finally conclude, in section IV, on the relevance of our dLLB model, when the auto-correlation time for the bath variables is no longer negligible, and present some ideas about the situations where our closure assumptions may break down and, therefore, when the validity of our model attains its limits.

II. NON-MARKOVIAN SLLG MODELLING

The Einstein summation convention is used throughout, with Latin indices standing for vector components, \( \epsilon_{ijk} \) is the anti-symmetric Levi-Civita pseudo-tensor and \( s_i \) denotes the component of the normalized magnetization vector (\( |\vec{s}| = 1 \)).
Up to a renormalization over the noise \[15\], the stochastic Landau-Lifshitz-Gilbert (sLLG) equation can be written as follows:

\[
\frac{\partial s_i}{\partial t} = \frac{1}{1 + \lambda^2} \varepsilon_{ijk} s_k [\omega_j + \tilde{\omega}_j - \lambda \varepsilon_{jlm} \omega_l s_m] \quad (2)
\]

with \(\omega_j\) the precession frequency assumed independent of the spin state and \(\tilde{\omega}_j\) describes the (fluctuating) contribution of the thermal bath.

When the \(\tilde{\omega}\) become non-Markovian random variables, drawn from a Gaussian distribution, defined by the autocorrelation functions \[1\], the sLLG equation (eq. 2) can be recast into the following set of equations \[16\], \[17\]:

\[
\frac{\partial s_i}{\partial t} = \frac{1}{1 + \lambda^2} \varepsilon_{ijk} s_k [\omega_j + \tilde{\omega}_j - \lambda \varepsilon_{jlm} \omega_l s_m] \quad (3)
\]

\[
\frac{\partial \tilde{\omega}_j}{\partial t} = -\frac{1}{\tau} (\tilde{\omega}_j - \xi_j) \quad (4)
\]

and where \(\xi\) are new Gaussian random variables, such that: \(\langle \xi_j (t) \rangle = 0\) and \(\langle \xi_i(t) \xi_j(t') \rangle = 2D \delta_{ij} \delta (t-t')\).

The bath variables are now, themselves, solutions of a stochastic differential equation. This, indeed, is what introduces inertial effects, that are described by the auto-correlation time \(\tau\).

An interesting feature of this new set of equations is that, for the case of no transverse damping (\(\lambda = 0\) in eq. 3), we immediately recover the formalism developed by Myasakali and Seki (MS) \[13\]. In this way, the set of equations (3,4) can be seen as a generalization of their work in the case of finite transverse damping.

However, their equation on the bath variables takes a slightly different form than in our work, because they introduced a phenomenological form of damping, that depends on the magnetization state and with a spin coupling constant \(\chi\). The dynamics of \(\tilde{\omega}\) is indeed damped by a factor that depends on the value of the magnetization, and therefore, the corresponding distribution (for the bath variable) has no reason to remain Gaussian (especially in the case of a non-trivial Hamiltonian for the spin system). In our case, by construction, it is ensured that the bath variables \(\tilde{\omega}_i\) are, both, always drawn from a Gaussian distribution, and remain sensitive to the inertial effects of the memory kernel, defined by the color of the noise.

This set of equations (3) and (4) is then integrated using a third-order Omelyan’s algorithm \[19\], \[20\] that respects the symplectic properties of equation (3). Regarding the noise, this system is formally integrated as \(\tilde{\omega}_i(t) = e^{tL} \tilde{\omega}(0) = \int_0^t e^{-(t-u)/\tau} \xi_i(u)du\) with \(L\tilde{\omega}\) is the Liouville operator corresponding to Eq. (4). Because the Liouville operators of the spin and the noise commute, an integration of the colored system is performed by the combination of the two operators as \(e^{tL} (s_i(0), \tilde{\omega}_i(0)) = e^{tL} e^{tL\tilde{\omega}} (s_i(0), \tilde{\omega}_i(0)) = (s_i(t), \tilde{\omega}_i(t))\).

It should be stressed that this scheme indeed incorporates the Stratonovich Ansatz, whose theoretical foundations have been studied by Aron et al. \[21\] for the case of the sLLG.

An effective averaging model is then constructed: the integration of the set of stochastic equations (3,4) is performed one thousand times, each time for a different realization of the random variables \(\xi_i\). The results for the spin realizations are stored, and statistical averages thereof are computed. This methodology presents, of course, some disadvantages: first of all, that it is purely computational; also, that it requires significant storage for the configurations. However, these are more than compensated for by the fact that it provides an exact formulation and resolution of the Langevin-like stochastic equation (our non-Markovian sLLG equation). Fig. 1 presents some results directly obtained with the effective averaging model.

![Figure 1](image_url)

Figure 1. Comparisons between simulations performed with the effective stochastic model, for two different values of the auto-correlation time: \(\tau = 10^{-7}\) above, and \(\tau = 10^{-2}\) below. The red curves plot the dynamics of a component of the averaged magnetization vector ((\(s_x\))) in a constant magnetic field in the \(z\)-direction, and the blue curves plot the square of the averaged magnetization norm, for different repetition values \(N\) (\(N=1, 10\) and 1000). Parameters of the simulations: \(D = 1\) rad.GHz; \(\lambda = 0.1\); \(\omega = (0, 0, \omega_z)\), with \(\omega_z = 176\) rad.GHz; timestep \(\Delta t = 10^{-7}\) ns. Initial conditions: \(\vec{s}(0) = (1, 0, 0)\).

Fig. 1 highlights the following interesting features of our system: A first, very important, result is that, for the case \(N = 1\), that plots two stochastic simulations, without any averaging effects, increasing the auto-correlation time, \(\tau\), leads to stronger inertial effects, that can be directly seen from the curves of \(\langle s_x \rangle\). Indeed, from fig. 1 we can deduce that this variation does not have a strong impact on the amplitude of the fluctuations of \(\langle s_x \rangle\), but tends to smoothen them out.

Some other features can be observed, concerning the square of the averaged magnetization norm. First, when \(N = 1\), the norm of the magnetization remains perfectly constant and equal to unity (without any renormalization necessary over the time steps). This is a good test of the validity of the integration scheme that has been applied, and therefore make all our procedures (eqs. (3) and (4), and the integration scheme) a good framework for non-Markovian atomistic simulations. Moreover, when the number \(N\), of realizations increases (which is equivalent to a better approximation of the statistically averaged quantities), the square of the averaged magnetization norm stabilizes below unity. This constitutes a simple and very direct recovery of the equivalence between the presence of a longitudinal form of damping, and statistical
averaging in a thermalized magnetic system.

Therefore, the behavior in time of the average magnetization dynamics (that our dLLB model is expected to track) can be used to realize direct comparisons between the two models, for the same set of parameters.

III. TESTING THE LIMITS OF THE AUTO-CORRELATION TIME EFFECTS

The set of statistically averaged equations, called dLLB model, is now introduced. With \( \langle \cdot \rangle \) denoting the statistical average over the noise, one has the following set of 21 equations:

\[
\frac{\partial (s_i)}{\partial t} = \frac{1}{1 + \lambda^2} \left[ \epsilon_{ijk} \omega_j \langle s_k \rangle + \epsilon_{ijk} \langle \tilde{\omega}_j s_k \rangle \right]
- \lambda \epsilon_{ijk} \epsilon_{jlm} \omega_l \langle s_k s_m \rangle \tag{5}
\]

\[
\frac{\partial \langle \tilde{\omega}_i s_j \rangle}{\partial t} = -\frac{1}{\tau} \langle \tilde{\omega}_i s_j \rangle + \frac{1}{1 + \lambda^2} \left[ \epsilon_{jkl} \omega_k \langle \tilde{\omega}_i s_l \rangle \\
+ \frac{D}{\tau} \epsilon_{jkl} \langle s_l \rangle - \lambda \epsilon_{jkl} \epsilon_{kmn} \omega_m \langle \langle s_l \rangle \langle \tilde{\omega}_i s_n \rangle \rangle \\
+ \langle s_n \rangle \langle \tilde{\omega}_i s_l \rangle \right] \tag{6}
\]

\[
\frac{\partial \langle s_i s_j \rangle}{\partial t} = \frac{1}{1 + \lambda^2} \left[ \epsilon_{jkl} \omega_k \langle s_i s_l \rangle \\
+ \epsilon_{jkl} \langle \langle s_l \rangle \langle \tilde{\omega}_k s_i \rangle + \langle s_l \rangle \langle \tilde{\omega}_k s_i \rangle \rangle \\
- \lambda \epsilon_{jkl} \epsilon_{kmn} \omega_m \langle \langle s_l \rangle \langle s_i s_n \rangle \rangle \\
+ \langle s_l \rangle \langle s_i s_n \rangle + \langle s_i \rangle \langle s_i s_n \rangle - 2 \langle s_l \rangle \langle s_i \rangle \langle s_n \rangle \right] \\
+ \langle s_l \rangle \langle \tilde{\omega}_i s_l \rangle \tag{7}
\]

Equations (5) and (7) are strongly related to those derived by Garanin et al. [4], and obtained under slightly different assumptions. Equation (6) is deduced from the application of the Shapiro-Loginov formula [14], and defines the time evolution of the mixed moments of the thermal bath variables and the spin system variables.

This model was only shown to be valid for the simulation of averaged magnetization dynamics in interaction with a constant magnetic field, and when the auto-correlation time can be considered to be “small” (i.e. close to the Markovian limit) [13]. Under those conditions, the Gaussian assumptions that have been applied to the moments (and that allowed us to close the hierarchy of moments and to integrate our dLLB model) hold.

We now want to probe the range of validity of our closure assumptions for other values of the auto-correlation time \( \tau \). This is possible via a direct comparison between our dLLB set of equations and the effective averaging model. Figures [2] and [3] plot these comparisons for two very different values of the auto-correlation time \( \tau \).

For weakly correlated noise (\( \tau = \Delta t \)), fig. [2] shows an excellent agreement between the two models. The value of the auto-correlation time, \( \tau \), was then increased, while keeping the value of the amplitude of the noise, \( D \), fixed. As shown in fig. [3] the results of the two models only begin to diverge one from the other for “strongly” auto-correlated noise (\( \tau = 10^{-2} \) ns).

Several orders of magnitude separate the two values of the auto-correlation time \( \tau \); nonetheless, we remark that our results provide evidence that our dLLB model and the related closure assumptions remain valid, also, for strongly non-Markovian noise.

Both stochastic and deterministic curves of fig. [2] and [3] are strongly smoothed by the averaging. Therefore, the difference in terms of inertial effects, between the strongly and slightly Markovian cases (when \( \tau = 10^{-2} \), or \( \tau = 10^{-7} \), respectively) is barely observable (unlike it was on fig. [1] for the situations of small realization numbers, \( N=1 \) and 10). But an interesting feature, that is recovered from the comparison of the two graphs, is that increasing the auto-correlation time leads, on average, to an enhancement of longitudinal damping effects. An equivalent result was already observed by Atxitiia et al. [7] in atomistic non-Markovian simulations, performed with
the Myasaki and Seki (MS) model.

IV. CONCLUSION

An integration method for the non-Markovian sLLG equation was presented. This scheme allows us to construct an effective averaging model that solves the stochastic Langevin-like equation, for a fixed realization of the non–Markovian noise process and construct the magnetization correlation functions from the many realizations that were drawn—the only limitation is storage for the configurations.

A first set of numerical experiments was performed with this effective averaging model (results plotted on fig. 1). It allowed us to test the consistency of our integration scheme, and to probe the effects of the auto-correlation time \( \tau \) on the magnetization dynamics. Inertial effects were clearly observed with the variations of \( \tau \), and the influence of statistical averaging on the magnetization norm was also recovered (equivalence between statistical averaging and longitudinal form of damping in a magnetic system connected to a thermal bath).

Then, comparisons between the numerical results obtained from this model and our previously derived dLLB set of equations were carried out. These simulations lead us to two main conclusions. First, it was shown that, even across large intervals of values of the auto-correlation time \( \tau \) (from weakly correlated noise, \( \tau = 10^{-7} \) ns, to clearly non-Markovian cases, \( 10^{-2} \) ns), the closure assumptions of our hierarchy of equations hold, and our dLLB model remains valid. The application of these techniques also allowed us to recover the result that increasing the auto-correlation time for the bath variables not only enhances their inertial effects, but can also lead to stronger longitudinal damping effects, that can be measured in the average magnetization dynamics.

In future work [22], it will be shown that what does affect the closure assumptions and the validity of our model are the magnetic interactions that are taken into account, for example, the contribution of a uniaxial anisotropy, or an exchange interaction.

In this case, it was observed that cumulants of the spin and bath variables, assumed to be equal to zero under Gaussian assumptions, are no longer taking negligible values (like the third order cumulants of the spin, for example). Therefore, non–Gaussian closure assumptions are required, and a particular attention has to be taken for the treatment of the mixed (noise and spin) moments. The stochastic approach to chaotic dynamical systems [23] may provide valuable insights to this end.
