Abstract

The presence of several clone solutions in the simultaneous measurement of \((\theta_{13}, \delta)\) has been widely discussed in literature. In this letter we write the analytical formulæ of the clones location in the \((\theta_{13}, \delta)\) plane as a function of the physical input pair \((\bar{\theta}_{13}, \bar{\delta})\). We show how the clones move with changing \(\bar{\theta}_{13}\). The “clone flow” can be significantly different if computed (naively) from the oscillation probabilities or (exactly) from the probabilities integrated over the neutrino flux and cross-section.

Using our complete computation we compare the clone flow of a set of possible future neutrino experiments: the CERN SuperBeam, BetaBeam and Neutrino Factory proposals. We show that the combination of these specific BetaBeam and SuperBeam does not help in solving the degeneracies. On the contrary, the combination of one of them with the Neutrino Factory Golden and Silver channel can be used, from a theoretical point of view, to solve completely the eightfold degeneracy.

1 Introduction

The atmospheric and solar sector of the PMNS leptonic mixing matrix [1] have been measured with quite good resolution by SK [2], SNO [3] and KamLand [4]. These experiments measure two angles, $\theta_{12}$ and $\theta_{23}$, and two mass differences, $\Delta m_{12}^2$ and $\Delta m_{23}^2$ (for the explicit form of the PMNS matrix and the adopted conventions, see for example [5]). The present bound on $\theta_{13}$, $\sin^2 \theta_{13} \leq 0.02$, is extracted from the negative results of CHOOZ [6] and from three-family analysis of atmospheric and solar data. The PMNS phase $\delta$ is totally unbounded as no experiment is sensitive to the leptonic CP violation. The main goal of next neutrino experiments will be to measure these two still unknown parameters of the leptonic mixing matrix. In this paper we concentrate on analyzing, form a theoretical point of view, a particular problem that arise when trying to measure simultaneously $(\theta_{13}, \delta)$.

In [7] it has been noticed that the appearance probability $P_{\alpha\beta}(\bar{\theta}_{13}, \bar{\delta})$ obtained for neutrinos at a fixed energy and baseline with input parameter $(\bar{\theta}_{13}, \bar{\delta})$ has no unique solution. Indeed, the equation:

$$P_{\alpha\beta}(\bar{\theta}_{13}, \bar{\delta}) = P_{\alpha\beta}(\theta_{13}, \delta) \quad (1)$$

has a continue number of solutions. The locus of $(\theta_{13}, \delta)$ satisfying this equation is called “equiprobability curve”. Considering the equiprobability curves for neutrinos and antineutrinos with the same energy (and the same input parameters), the system of equations

$$P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}) = P_{\alpha\beta}^\pm(\theta_{13}, \delta) \quad (2)$$

(where $\pm$ refers to neutrinos and antineutrinos) has two intersections: the input pair $(\bar{\theta}_{13}, \bar{\delta})$ and a second, energy dependent, point. This second intersection introduces an ambiguity in the measurement of the physical values of $\theta_{13}$ and $\delta$: the so-called intrinsic clone. As it was made clear in [8, 9], two other sources of ambiguities are present:

- We only know the absolute value [2], $|\Delta m_{23}^2| \in [1.9, 3.5] \times 10^{-3}$ eV$^2$ of the atmospheric mass difference, not its sign. This ambiguity originates from the fact that atmospheric neutrino experiments measure only the leading oscillation $\nu_\mu \rightarrow \nu_\tau$ that depends quadratically on $\Delta m_{23}^2$;

- We only know the allowed departure of $\theta_{23}$ from maximal mixing, $\sin^2 2\theta_{23} > 0.9$, but not if $\theta_{23}$ is actually smaller or greater than 45°. This ambiguity originates in that neutrino experiments are looking for $\nu_\mu, \nu_e$ disappearance or $\nu_\mu \rightarrow \nu_\tau$ oscillation, where $\theta_{23}$ appears only through $\sin^2 2\theta_{23}$.

As a consequence, future experiments will have as ultimate goal the measure of the two continuous variables $\theta_{13}$ and $\delta$ plus the two discrete variables:

$$\bar{s}_{atm} = \text{sign}[\Delta m_{23}^2], \quad \bar{s}_{oct} = \text{sign}[\tan(2\theta_{23})]. \quad (3)$$
These two discrete variables assume the values ±1, depending on the physical assignments of the \( \Delta m_{23}^2 \) sign (\( s_{atm} = 1 \) for \( m_3^2 > m_2^2 \) and \( s_{atm} = -1 \) for \( m_3^2 < m_2^2 \)) and of the \( \theta_{23} \)-octant (\( s_{oct} = 1 \) for \( \theta_{23} < \pi/4 \) and \( s_{oct} = -1 \) for \( \theta_{23} > \pi/4 \)). As a consequence, taking into account all the present ignorance on the neutrino mixing and masses, eq. (2) must be rewritten, more precisely, as:

\[
P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; \bar{s}_{atm}, \bar{s}_{oct}) = P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm} = \bar{s}_{atm}; s_{oct} = \bar{s}_{oct}),
\]

where \( \bar{s}_{atm} \) and \( \bar{s}_{oct} \) have been included as input parameters in addition to \( \bar{\theta}_{13} \) and \( \bar{\delta} \). In eq. (5) we have implicitly assumed to know the right sign and the right octant for the atmospheric mass difference and angle. As these quantities are unknown (and presumably they will remain so at the time of the next neutrino facilities), all the following equiprobabilities systems of equations should be considered as well:

\[
P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm}, \bar{s}_{oct}) = P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm} = -\bar{s}_{atm}; s_{oct} = \bar{s}_{oct}),
\]

\[
P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm}, \bar{s}_{oct}) = P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm} = \bar{s}_{atm}; s_{oct} = -\bar{s}_{oct}),
\]

\[
P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm}, \bar{s}_{oct}) = P_{\alpha\beta}^\pm(\bar{\theta}_{13}, \bar{\delta}; s_{atm} = -\bar{s}_{atm}; s_{oct} = -\bar{s}_{oct}).
\]

These new sets of equiprobability systems arise when we equate the true probability (left hand side) with the probabilities obtained including one of the three possible wrong guesses on \( s_{atm} \) and \( s_{oct} \) (right hand side).

Solving the four systems of eq. (5)-8 will result in obtaining the true solution plus the appearance of additional clones to form an eightfold-degeneracy. These eight solutions are respectively:

- the true solution and its intrinsic clone, obtained solving the system of eq. (5);
- the \( \Delta m_{23}^2 \)-sign clones (hereafter called sign clones) of the true and intrinsic solution, obtained solving the system of eq. (6);
- the \( \theta_{23} \)-octant clones (hereafter called octant clones) of the true and intrinsic solution, obtained solving the system of eq. (7);
- the \( \Delta m_{atm}^2 \)-sign \( \theta_{23} \)-octant clones (hereafter called mixed clones) of the true and intrinsic solution, obtained solving the system of eq. (8).

In the following section we illustrate the technique used for calculating the location of the clone solutions. We describe explicitly the formulae for the \( \nu_e \to \nu_\mu \) oscillation probability, due to the great importance it has in literature. In fact this “golden” channel (together with its CP conjugate channel) has been shown to be very promising to simultaneously study the \( \theta_{13} \) angle and the leptonic CP-violation at the Neutrino Factory and in the BetaBeam based facilities. Anyway most of the considerations done apply as well to the time reversal transitions \( \nu_\mu \to \nu_e \) (and the CP conjugate one) that has been considered in the context of SuperBeam facilities like the SPL CERN project. The same strategy will be applied in Sect. (3.3) to the study of the \( \nu_e \to \nu_\tau \) transition (the so-called “silver channel”) at a Neutrino Factory. As pointed out in this channel can become very useful in reducing the number of clone solutions.
2 Probability vs Number of Events

Following eq. (1) of [7], the appearance probability for the $\nu_e \rightarrow \nu_\mu$ ($\bar{\nu}_e \rightarrow \bar{\nu}_\mu$) transition, expanded at second order in perturbation theory in $\theta_{13}, \Delta_{12}/\Delta_{23}, \Delta_{12}/A$ and $\Delta_{12}L$ (see also [16, 17]), reads:

$$P_{\nu_\mu}^{\pm}(\bar{\theta}_{13}, \bar{\delta}) = X_{\pm} \sin^2(2\bar{\theta}_{13}) + Y_{\pm} \cos(\bar{\theta}_{13}) \sin(2\bar{\theta}_{13}) \cos\left(\pm\bar{\delta} - \frac{\Delta_{23}L}{2}\right) + Z,$$

where $\pm$ refers to neutrinos and antineutrinos, respectively. The coefficients $X_{\pm}, Y_{\pm}$ and $Z$ are defined as follows:

$$X_{\pm} = \sin^2(\theta_{23}) \left(\frac{\Delta_{23}}{B_{\bar{\pi}}}\right)^2 \sin^2\left(\frac{B_{\bar{\pi}}L}{2}\right),$$

$$Y_{\pm} = \sin(2\theta_{12}) \sin(2\theta_{23}) \left(\frac{\Delta_{12}}{A}\right) \left(\frac{\Delta_{23}}{B_{\bar{\pi}}}\right) \sin\left(\frac{AL}{2}\right) \sin\left(\frac{B_{\bar{\pi}}L}{2}\right),$$

$$Z = \cos^2(\theta_{23}) \sin^2(2\theta_{12}) \left(\frac{\Delta_{12}}{A}\right)^2 \sin^2\left(\frac{AL}{2}\right),$$

with $A = \sqrt{2}G_F n_e$ (expressed in eV$^2$/GeV) and $B_{\bar{\pi}} = |A \mp \Delta_{23}|$. Finally, $\Delta_{23} = \Delta m^2_{23}/2E_\nu$ and $\Delta_{12} = \Delta m^2_{12}/2E_\nu$. Instead of using the coefficients in eqs. (10-12), it is convenient [18] to introduce the following ($\theta_{13}, \delta$)-independent terms:

$$O_{1}^{\pm} = X_{\pm}, \quad O_{2}^{\pm} = Y_{\pm} \cos\left(\frac{\Delta_{23}L}{2}\right), \quad O_{3}^{\pm} = Y_{\pm} \sin\left(\frac{\Delta_{23}L}{2}\right), \quad O_{4} = Z. \quad (13)$$

Notice, however, that transition probabilities, like for example $P_{\nu_\mu}^{\pm}$, are not the experimentally “measured” quantities. Experimental results are given in terms of the number of charged leptons observed in a specific detector. For the Neutrino Factory Golden channel, for example, one measures the number of interacting muons with charge opposite to those circulating in the storage ring. In a SuperBeam-driven detector the signal is, on the other hand, represented by electrons. If the considered detector can measure the lepton and hadron final energies, $E_l, E_h$ with a good resolution, the events are then grouped in bins of energy interval $\Delta E_l$. This is indeed the case for the proposed Magnetized Iron Calorimeter (MIC) [19] at the Neutrino Factory, where the number of muons in the i-th energy bin for the input pair $(\bar{\theta}_{13}, \bar{\delta})$ and for a parent muon energy $\bar{E}_\mu$ is given by:

$$N_{\mu^+}^{\gamma}(\bar{\theta}_{13}, \bar{\delta}) = \left\{ \frac{d\sigma_{\nu_\mu}(E_\mu, E_\nu)}{dE_\mu} \otimes P_{\nu_\mu}^{\pm}(E_\nu, \bar{\theta}_{13}, \bar{\delta}) \otimes \frac{d\Phi_{\nu_\mu}(E_\nu, \bar{E}_\mu)}{dE_\nu} \right\}_{E_{1i} + \Delta E_l}^{E_l} \quad (14)$$

where $\otimes$ stands for a convolution integral [14]. The same happens for the Emulsion Cloud Chamber (ECC) [15] (see Sect. 3.3 for details). On the contrary, whenever the considered detector energy resolution is not sufficient to group events in bins of energy, one single sample will be considered. This is for example the case for the Water Cherenkov detector.
located at the Frejus as the target of a SuperBeam (SB) or Beta-Beam (BB) experiments, as we can read from [12].

Using the \( O_j \) coefficients in eq. (13) we define the following integrals:

\[
I_j^\pm = \left\{ \frac{d\sigma_{\nu\nu}(E_\mu, E_\nu)}{dE_\mu} \otimes O_j^\pm(E_\nu) \otimes \frac{d\Phi_{\nu\nu}(E_\nu, E_\mu)}{dE_\nu} \right\}_{E_i}^{E_i+\Delta E_\mu},
\]

where the \( O_j \) coefficients are convoluted over the \( \nu N \) cross-section and the differential neutrino flux. All the experimental details, such as the flux shape, the cross-section, the baseline and the solar, atmospheric and matter parameters are encoded in these integrals. The number of events in the \( i \)-th bin, in the same approximation used for eqs. (9), is therefore:

\[
N_{i \mu^-} = \left\{ I_1^+ \sin^2(2\theta_{13}) + I_2^+ \cos \delta + I_3^+ \sin \delta \right\} \cos \theta_{13} \sin(2\theta_{13}) + I_4^+ \right\}^{i},
\]

\[
N_{i \mu^+} = \left\{ I_1^- \sin^2(2\theta_{13}) + I_2^- \cos \delta - I_3^- \sin \delta \right\} \cos \theta_{13} \sin(2\theta_{13}) + I_4^- \right\}^{i}.
\]

For a specific energy bin and fixed input parameters \((\bar{\theta}_{13}, \bar{\delta})\), we derive the clone location in the \((\theta_{13}, \delta)\) plane solving:

\[
N_{i \mu^+}^\pm (\bar{\theta}_{13}, \bar{\delta}; \bar{s}_{atm}, \bar{s}_{oct}) = N_{i \mu^+}^\pm (\theta_{13}, \delta; s_{atm} = \bar{s}_{atm}, s_{oct} = \bar{s}_{oct})
\]

\[
N_{i \mu^-}^\pm (\bar{\theta}_{13}, \bar{\delta}; \bar{s}_{atm}, \bar{s}_{oct}) = N_{i \mu^-}^\pm (\theta_{13}, \delta; s_{atm} = \bar{s}_{atm}, s_{oct} = \bar{s}_{oct})
\]

\[
N_{i \mu^+}^\pm (\bar{\theta}_{13}, \bar{\delta}; \bar{s}_{atm}, \bar{s}_{oct}) = N_{i \mu^+}^\pm (\theta_{13}, \delta; s_{atm} = -\bar{s}_{atm}, s_{oct} = \bar{s}_{oct})
\]

\[
N_{i \mu^-}^\pm (\bar{\theta}_{13}, \bar{\delta}; \bar{s}_{atm}, \bar{s}_{oct}) = N_{i \mu^-}^\pm (\theta_{13}, \delta; s_{atm} = -\bar{s}_{atm}, s_{oct} = -\bar{s}_{oct})
\]

as it was the case for the transition probability in eqs. (9-11).

3 Location of the clones

In this section we determine the analytic expression for the clone location, in the case of \( \nu_e \rightarrow \nu_\mu \) oscillations, solving the integrated systems in eqs. (17-20). We are going to describe completely the procedure for calculating the intrinsic clone and then we present, for all the cases, the simplified vacuum formulæ. A detailed derivation is deferred to Appendix A. Moreover, in order to simplify the notation, from now on we will omit any reference to the bin index \( i \) in the convolution integrals, eq. (15).

3.1 The intrinsic clone

We derive now the theoretical solution of eq. (17) following the outline of [14]. This equation corresponds to the particular case \( s_{atm} = \bar{s}_{atm}; s_{oct} = \bar{s}_{oct} \). The explicit results that we get for \( \delta \) and \( \theta_{13} \) can be compared with [7-14].
Eq. (17) draws two continuous equal-number-of-events (ENE) lines in the $(\theta_{13}, \delta)$ plane. We derive an implicit equation in $\delta$:

$$F^\pm(\delta) = G^\pm(\theta_{13}, \bar{\theta}_{13}, \tilde{\delta}),$$  
(21)

where

$$F^\pm(\delta) = \cos \delta \pm \left( \frac{I^\pm_3}{I^\pm_2} \right) \sin \delta$$  
(22)

and

$$G^\pm(\theta_{13}, \bar{\theta}_{13}, \tilde{\delta}) = \left( \frac{I^\pm_1}{I^\pm_2} \right) f(\theta_{13}, \bar{\theta}_{13}) + F^\pm(\tilde{\delta}) g(\theta_{13}, \bar{\theta}_{13}).$$  
(23)

The two $\theta_{13}$-dependent functions, $f$ and $g$, are:

$$f(\theta_{13}, \bar{\theta}_{13}) = \frac{\sin^2(2\bar{\theta}_{13}) - \sin^2(2\theta_{13})}{\cos \theta_{13} \sin(2\theta_{13})}$$

$$g(\theta_{13}, \bar{\theta}_{13}) = \frac{\cos \bar{\theta}_{13} \sin(2\bar{\theta}_{13})}{\cos \theta_{13} \sin(2\theta_{13})}$$  
(24)

This parametrization is valid for any value of $\bar{\theta}_{13}$, including $\bar{\theta}_{13} \to 0$: not an irrelevant feature, since even in the case of vanishing $\bar{\theta}_{13}$ clone solutions with a non null value of $\theta_{13}$ can appear. In this case a totally wrong conclusion about the value of $\bar{\theta}_{13}$ can indeed originate by a naive analysis of the experimental results. Notice, finally, the trivial limits $f(\bar{\theta}_{13}, \bar{\theta}_{13}) = 0$ and $g(\bar{\theta}_{13}, \bar{\theta}_{13}) = 1$.

Solving the system in eq. (21), we derive two equations for $\sin \delta$ and $\cos \delta$:

$$\sin \delta = C f(\theta_{13}, \bar{\theta}_{13}) + g(\theta_{13}, \bar{\theta}_{13}) \sin \bar{\delta}$$

$$\cos \delta = D f(\theta_{13}, \bar{\theta}_{13}) + g(\theta_{13}, \bar{\theta}_{13}) \cos \bar{\delta}$$  
(25)

where the coefficients are

$$C = \left[ \frac{I^+_1 I^+_2 - I^-_1 I^-_2}{I^+_3 I^+_2 + I^-_3 I^-_2} \right], \quad D = \left[ \frac{I^+_1 I^-_3 + I^-_1 I^+_3}{I^+_3 I^+_2 + I^-_3 I^-_2} \right].$$  
(26)

In the following results, the baseline and energy bin dependence appears only through these integral ratios. Notice that only three of the four integrals $I^\pm_j$ are present in $C$ and $D$. In fact, there is no dependence on $I_4$ due to the fact that for $s_{\text{oct}} = \bar{s}_{\text{oct}}$ this integral drops between left and right hand sides of eq. (16).

In the approximation $\cos \theta_{13} \simeq \cos \bar{\theta}_{13} \simeq 1$, perfectly valid since $\theta_{13} \leq 10^\circ$ [6], we solve eq. (25) for $\theta_{13}$ to get:

$$\sin^2 2\theta_{13} = \left\{ \begin{array}{ll}
\sin^2 2\bar{\theta}_{13} \\
\sin^2 2\bar{\theta}_{13} + 1 + 2 \left[ \frac{D \cos \bar{\delta} + C \sin \bar{\delta}}{C^2 + D^2} \right] \sin 2\bar{\theta}_{13}
\end{array} \right.$$

$$= \left\{ \begin{array}{ll}
\sin^2 2\bar{\theta}_{13} \\
1 + 2 \left[ \frac{D \cos \bar{\delta} + C \sin \bar{\delta}}{C^2 + D^2} \right] \sin 2\bar{\theta}_{13}
\end{array} \right.$$

$$= \left\{ \begin{array}{ll}
\sin^2 2\bar{\theta}_{13} \\
1 + 2 \left[ \frac{D \cos \bar{\delta} + C \sin \bar{\delta}}{C^2 + D^2} \right] \sin 2\bar{\theta}_{13}
\end{array} \right.$$

$$= \left\{ \begin{array}{ll}
\sin^2 2\bar{\theta}_{13} \\
1 + 2 \left[ \frac{D \cos \bar{\delta} + C \sin \bar{\delta}}{C^2 + D^2} \right] \sin 2\bar{\theta}_{13}
\end{array} \right.$$  
(27)
in which the first solution represents the true input value $\theta_{13} = \bar{\theta}_{13}$ and the second one the location of the intrinsic clone. Eventually, substituting the results of eq. (27) into $f(\theta_{13}, \bar{\theta}_{13})$ and $g(\theta_{13}, \bar{\theta}_{13})$, we can get the value of $\delta$ for the intrinsic clone using one of the relations in eq. (25).

It is interesting to specialize these results to the case of very short baseline $L$, where matter effects can be neglected. In the vacuum approximation, the convolution integrals of the four $O_j$ coefficients no longer differ for neutrinos and antineutrinos, $\lim_{A \to 0} I_{j}^+ = I_{j}$. As a consequence,

$$\lim_{A \to 0} C = 0 \quad \lim_{A \to 0} D = \frac{I_1}{I_2}$$

and

$$\sin \delta = g(\theta_{13}, \bar{\theta}_{13}) \sin \bar{\delta}$$  \hspace{2cm} (29)$$

$$\cos \delta = \frac{I_1}{I_2} f(\theta_{13}, \bar{\theta}_{13}) + g(\theta_{13}, \bar{\theta}_{13}) \cos \bar{\delta}$$

The location of the intrinsic clone in vacuum is:

$$\sin^2 2\theta_{13} = \sin^2 2\bar{\theta}_{13} + \left( \frac{I_2}{I_1} \right)^2 \left[ 1 + 2 \left( \frac{I_1}{I_2} \right) \cos \bar{\delta} \sin 2\bar{\theta}_{13} \right].$$  \hspace{2cm} (30)$$

Notice that in vacuum the clone location depends on $I_1$ and $I_2$, only: the dependence on $I_3$ has also dropped from eq. (29). Eq. (30) generalizes the results of [7] and [13], where two regimes ("atmospheric" and "solar", for large and small $\bar{\theta}_{13}$, respectively) are discussed independently. In particular, at first order in $I_2/I_1$ our vacuum solution for $\theta_{13}$ reproduces eq. (5) of [13], valid in the atmospheric regime:

$$\sin^2 2\theta_{13} \simeq \sin^2 2\bar{\theta}_{13} + 2 \frac{I_2}{I_1} \cos \bar{\delta} \sin 2\bar{\theta}_{13}$$  \hspace{2cm} (31)$$

$$\cot \delta \simeq - \cot \bar{\delta} - \frac{I_2}{I_1 \sin 2\theta_{13}} \frac{1}{\sin \delta}$$  \hspace{2cm} (32)$$

For values of $\bar{\theta}_{13}$ large enough, $\delta \sim \pi - \bar{\delta} + \mathcal{O}(I_2/I_1)$.

### 3.2 Of other clones

The general case is represented by eq. (20). In this case, integrals on left and right hand side of eq. (16) are different and we can no longer factorize easily the $\theta_{13}$ dependence. As a consequence, the notation is going to be more involved with respect to the intrinsic case. To gain analytical insight of the results, however, we can carry on a bit more our mathematical manipulation. We label as $I_j$ the true integrals (on left hand side of eq. (16))
and $I_j$ those to be determined in the experiment (on right hand side of eq. (16)). We modify the functions in eq. (24) as follows:

$$
\begin{align*}
f'_\pm(\theta_{13}, \tilde{\theta}_{13}) &= \frac{\sin^2(2\tilde{\theta}_{13}) - [I_1^\pm / I_1^\mp] \sin^2(2\theta_{13})}{\cos \theta_{13} \sin(2\theta_{13})}, \\
h'(\theta_{13}) &= \left(1 - I_4 / I_4\right) \frac{1}{\cos \theta_{13} \sin(2\theta_{13})},
\end{align*}
$$

with $f'_\pm(\theta_{13}, \tilde{\theta}_{13}) = f(\theta_{13}, \tilde{\theta}_{13})$ and $h'(\theta_{13}) = 0$ in the intrinsic case.

With these definitions we can rewrite eq. (23) as follows:

$$
G^\pm(\theta_{13}, \tilde{\theta}_{13}, \delta) = \left[\bar{I}_1^\pm f'_\pm(\theta_{13}, \tilde{\theta}_{13}) + \frac{\bar{I}_2^\pm}{I_2^\pm} F^\pm(\delta) g(\theta_{13}, \tilde{\theta}_{13}) + \frac{\bar{I}_4^\pm}{I_2^\pm} h'(\theta_{13}) \right],
$$

where, clearly,

$$
F^\pm(\delta) = \cos \delta \pm \left(\frac{\bar{I}_4^\pm}{I_2^\pm}\right) \sin \delta.
$$

In Tab. 1 we present the relation between the $\bar{I}_j$ true integrals and those that undergo a discrete $s_{\text{atm}}$ and/or $s_{\text{oct}}$ transformation. As it can be seen, the effect of $s_{\text{atm}} \to -s_{\text{atm}}$ is to flip neutrinos with antineutrinos (notice that $I_4$ is unaffected by this change). The change in the $\theta_{23}$ octant introduces a dependence on $\theta_{23}$ in $I_1$ and $I_4$, leaving $I_{2,3}$ unmodified. Using Tab. 1, we can specialize eq. (34) for the three ambiguities and derive analytical results for the sign, octant and mixed clones. These results are typically rather cumbersome and we refer the interested reader to Appendix A for the explicit analytical formulæ for the different clone locations.

| | Intrinsic: | Octant: | Sign: | Mixed: |
|---|---|---|---|---|
| $s_{\text{atm}} = \bar{s}_{\text{atm}}$ | $s_{\text{atm}} = \bar{s}_{\text{atm}}$ | $s_{\text{atm}} = -\bar{s}_{\text{atm}}$ | $s_{\text{atm}} = -\bar{s}_{\text{atm}}$ |
| $s_{\text{oct}} = \bar{s}_{\text{oct}}$ | $s_{\text{oct}} = -\bar{s}_{\text{oct}}$ | $s_{\text{oct}} = \bar{s}_{\text{oct}}$ | $s_{\text{oct}} = -\bar{s}_{\text{oct}}$ |
| $I_1^\pm$ | $\bar{I}_1^\pm$ | $\cot^2(\theta_{23}) \bar{I}_1^\pm$ | $\bar{I}_1^\mp$ | $\cot^2(\theta_{23}) \bar{I}_1^\mp$ |
| $I_2^\pm$ | $\bar{I}_2^\pm$ | $\bar{I}_2^\pm$ | $-\bar{I}_2^\pm$ | $-\bar{I}_2^\pm$ |
| $I_3^\pm$ | $\bar{I}_3^\pm$ | $\bar{I}_3^\pm$ | $\bar{I}_3^\pm$ | $\bar{I}_3^\pm$ |
| $I_4$ | $\bar{I}_4$ | $\tan^2(\theta_{23}) \bar{I}_4$ | $\bar{I}_4$ | $\tan^2(\theta_{23}) \bar{I}_4$ |

Table 1: Transformation laws of the integrals $I_j$ under the discrete ambiguities in the $\theta_{23}$ octant and in the $\Delta m_{23}^2$ sign.

We specialize here to the vacuum case. In this case, since the convolution integrals make no distinction between neutrinos and antineutrinos, the transformation properties of Tab. 1 simplify considerably. In particular, $I_3$ is unaffected by any of the discrete transformation; $I_2$ changes sign when $s_{\text{atm}} \to -s_{\text{atm}}$ and is unaffected by an octant shift;
\( I_1 \) and \( I_4 \) are unaffected by changes of \( s_{\text{atm}} \), whereas get a \( \theta_{23} \) dependence for an \( s_{\text{oct}} \) change. Notice that for \( \theta_{23} = 45^\circ \), only \( I_2 \) is sensitive to the sign of \( \Delta m_{23}^2 \).

The vacuum limit of eq. (33) is given by:

- **Intrinsic and Sign Clone**

  \[
  \begin{cases}
  f'_{\pm}(\theta_{13}, \bar{\theta}_{13}) \to f(\theta_{13}, \bar{\theta}_{13}) \\
  h'(\theta_{13}) \to 0
  \end{cases}
  \]  
  
  (36)

- **Octant and Mixed Clone**

  \[
  \begin{cases}
  f'_{\pm}(\theta_{13}, \bar{\theta}_{13}) \to f'_0(\theta_{13}, \bar{\theta}_{13}) = \frac{\sin^2(2\bar{\theta}_{13}) - \cot^2 \theta_{23} \sin^2(2\theta_{13})}{\cos \theta_{13} \sin(2\theta_{13})}, \\
  h'(\theta_{13}) \to h'_0(\theta_{13}) = (1 - \tan^2 \theta_{23}) \frac{1}{\cos \theta_{13} \sin(2\theta_{13})},
  \end{cases}
  \]

  (37)

Eq. (29) for \( \sin \delta \) becomes in vacuum:

\[
\sin \delta = g(\theta_{13}, \bar{\theta}_{13}) \sin \bar{\delta}
\]

(38)

for all the four clones. The equation for \( \cos \delta \) in vacuum is, on the other hand, different in the four cases:

- **Intrinsic Clone**: \( \cos \delta \)\_int = \( \frac{\bar{I}_1}{I_2} \) \( f(\theta_{13}, \bar{\theta}_{13}) \) + \( g(\theta_{13}, \bar{\theta}_{13}) \) \( \cos \bar{\delta} \)

- **Sign Clone**: \( \cos \delta \)\_sign = \( -\cos \delta \)\_int

- **Octant Clone**: \( \cos \delta \)\_oct = \( \frac{\bar{I}_1}{I_2} \) \( f'_0(\theta_{13}, \bar{\theta}_{13}) \) + \( g(\theta_{13}, \bar{\theta}_{13}) \) \( \cos \bar{\delta} \) + \( \frac{\bar{I}_4}{I_2} \) \( h'_0(\theta_{13}) \)

- **Mixed Clone**: \( \cos \delta \)\_mixed = \( -\cos \delta \)\_oct

Since the only difference for intrinsic and sign clones and for octant and mixed ones is a sign in front of the \( \cos \delta \) equation, we only get two vacuum solutions:

- **Intrinsic and Sign Clones**

  \[
  \sin^2 2\theta_{13} = \begin{cases}
  \sin^2 2\bar{\theta}_{13} \\
  \sin^2 2\bar{\theta}_{13} + \left( \frac{\bar{I}_2}{I_1} \right)^2 \left[ 1 + 2 \left( \frac{\bar{I}_1}{I_2} \right) \cos \bar{\delta} \sin 2\bar{\theta}_{13} \right]
  \end{cases}
  \]

  (39)
Octant and Mixed Clones

\[ \sin^2 2\theta_{13} = \sin^2 2\bar{\theta}_{13} + \]

\[ + \left\{ \tan^2 \theta_{23} \frac{\bar{I}_2}{\bar{I}_1} \left[ \cos \delta \sin 2\bar{\theta}_{13} + \tan^2 \theta_{23} \frac{\bar{I}_2}{2\bar{I}_1} \right] - \left( 1 - \tan^2 \theta_{23} \right) \left( \sin^2 2\bar{\theta}_{13} - \tan^2 \theta_{23} \frac{\bar{I}_4}{\bar{I}_1} \right) \right\} \]

\[ \pm \tan^2 \theta_{23} \frac{\bar{I}_2}{\bar{I}_1} \left\{ \left[ \cos \delta \sin 2\bar{\theta}_{13} + \tan^2 \theta_{23} \frac{\bar{I}_2}{2\bar{I}_1} \right]^2 - \left( 1 - \tan^2 \theta_{23} \right) \left( \sin^2 2\bar{\theta}_{13} - \tan^2 \theta_{23} \frac{\bar{I}_4}{\bar{I}_1} \right) \right\}^{1/2} \]

Notice that for the intrinsic and sign clones in vacuum, one solution is the true solution \( \theta_{13} = \bar{\theta}_{13} \) whereas the second solution get shifted with respect to \( \bar{\theta}_{13} \). This is not the case for the octant and mixed clones that, also in the vacuum limit, will undergo a shift with respect to \( \bar{\theta}_{13} \) for both solutions. Eq. (39) can be immediately recovered from eq. (40) for \( \theta_{23} = 45^\circ \).

The solution for the clone location along the \( \delta \) axis can be found using eq. (38). Notice that, due to property of the vacuum transition probabilities under a change in the sign of \( \Delta m^2_{23} \), the \( \delta \) shift for the sign and mixed clones is obtained replacing \( \delta\text{sign} = \pi - \delta\text{int} \) and \( \delta\text{mixed} = \pi - \delta\text{oct} \).

### 3.3 The \( \nu_e \rightarrow \nu_\tau \) transition

The results of Sect. 3.1 and 3.2 can be straightforwardly extended to the \( \nu_e \rightarrow \nu_\tau \) oscillations. In the same approximation used for eq. (2), we get for the oscillation probability:

\[ P_{\nu_e \rightarrow \nu_\tau} = X_{\nu_e \rightarrow \nu_\tau} \sin^2 (2\bar{\theta}_{13}) - Y_{\nu_e \rightarrow \nu_\tau} \cos (\bar{\theta}_{13}) \sin(2\bar{\theta}_{13}) \cos \left( \bar{\delta} - \frac{\Delta m^2_{23} L}{2} \right) + Z_{\nu_e \rightarrow \nu_\tau}, \]

with the following coefficients:

\[ X_{\nu_e \rightarrow \nu_\tau} = \cos^2 (\theta_{23}) \left( \frac{\Delta m^2_{23}}{B_{\tau}} \right)^2 \sin^2 \left( \frac{B_{\tau} L}{2} \right), \]

\[ Z_{\nu_e \rightarrow \nu_\tau} = \sin^2 (\theta_{23}) \sin^2 (2\bar{\theta}_{13}) \left( \frac{\Delta m^2_{12}}{A} \right)^2 \sin^2 \left( \frac{A L}{2} \right). \]

The coefficient \( Y_{\nu_e \rightarrow \nu_\tau} \) is defined in eq. (11), and it appears multiplied by a factor \((-1)\) with respect to the same term in eq. (9). The different correlation between \( \theta_{13} \) and \( \delta \) due to this sign has been shown to offer a possible solution of the intrinsic ambiguity at a Neutrino Factory, [14] [15].

Eq. (14) must be modified to take into account the \( \tau \rightarrow \mu \) branching ratio and the energy distribution of muons proceeding from a \( \tau \)-decay. The number of wrong-sign muons
in the detector is therefore:

\[
N_{\mu^\pm}(\bar{\theta}_{13}, \bar{\delta}) = BR(\tau \rightarrow \mu) \left\{ \left[ \frac{dN_{\mu^\pm}(E_\mu, E_\tau)}{dE_\mu} \otimes \frac{d\sigma_{\nu_e(\bar{\nu}_e)}(E_\tau, E_\nu)}{dE_\tau} \right] \otimes P^\pm_{e\bar{e}}(E_\nu, \bar{\theta}_{13}, \bar{\delta}) \otimes \frac{d\Phi_{\nu_e(\bar{\nu}_e)}(E_\nu, \bar{E}_\mu)}{dE_\nu} \right\}_{E_i}. 
\]

The integrals \( I_j \) are consequently:

\[
I_j = BR(\tau \rightarrow \mu) \left\{ \left[ \frac{dN_{\mu^\pm}(E_\mu, E_\tau)}{dE_\mu} \otimes \frac{d\sigma_{\nu_e(\bar{\nu}_e)}(E_\tau, E_\nu)}{dE_\tau} \right] \otimes O^\pm_j(E_\nu) \otimes \frac{d\Phi_{\nu_e(\bar{\nu}_e)}(E_\nu, \bar{E}_\mu)}{dE_\nu} \right\}_{E_i}. 
\]

The analytic results of Sect. 3.1 and 3.2 are formally extended to the \( \nu_e \rightarrow \nu_\tau \) oscillation replacing the \( I_j^{\mu} \) with \( I_j^{\tau} \) as follows:

\[
\begin{cases}
I_1^{\mu} & \rightarrow \tan^2 \theta_{23} I_1^{\tau} \\
I_2^{\mu} & \rightarrow -I_2^{\tau} \\
I_3^{\mu} & \rightarrow -I_3^{\tau} \\
I_4^{\mu} & \rightarrow \cot^2 \theta_{23} I_4^{\tau}.
\end{cases}
\]

4 The Degeneracies flow

In this section we will apply our analytic results to illustrate, from a theoretical point of view, where the different clones of the true solution, \((\bar{\theta}_{13}, \bar{\delta})\), are located in the \((\theta_{13}, \delta)\) plane for different experiments that have been discussed in the literature. The goal is to show which combination of experiments is better suited to solve some (or all) of the degeneracies. Notice that the existence of unresolved degeneracies could, in fact, manifests itself in a complete lost of predictability on the aforementioned parameters. It must be noticed that this analysis only provides a useful tool to detect the experiment synergies that are most promising to measure these two still unknown entries of the PMNS matrix. These results must then be confirmed by a detailed analysis in which statistics and systematics of a given experiment combination are carefully taken into account. This experimental analysis is well beyond the scope of this paper where we only focus in giving a theoretical insight of the problem.

The experiments that we have considered in our analysis are the following:

- A Neutrino Factory with 50 GeV muons circulating in the storage ring and two detectors: the first one located at \( L = 2810 \) Km is designed to look for the golden channel (hereafter labeled as NFG); the second one located at \( L = 732 \) Km is designed to look for the silver channel (hereafter labeled as NFS). The average neutrino energy is: \( < E_{\nu_e, \bar{\nu}_e} > \simeq 30 \) GeV.
• A SuperBeam with 2 GeV protons and one detector located at \( L = 130 \) Km to look for \( \nu_\mu \rightarrow \nu_e \) (hereafter labeled as SB). The average neutrino energy is: \( < E_{\nu_\mu} > \simeq 270 \) MeV and \( < E_{\bar{\nu}_\mu} > \simeq 250 \) MeV.

• A Beta Beam with \(^6\text{He}\) and \(^{18}\text{Ne}\) ions and one detector located at \( L = 130 \) Km to look for \( \nu_e \rightarrow \nu_\mu \) (hereafter labeled as BB). The average neutrino energy is: \( < E_{\nu_e} > \simeq 360 \) MeV and \( < E_{\bar{\nu}_e} > \simeq 240 \) MeV.

Notice that for our theoretical analysis the details of the detectors (such as the mass or the specific technology adopted to look for a given signal) are irrelevant, since they cancel between left and right hand side of eqs. (17)-(20). However, the relevant parameters (the neutrino fluxes and the baseline) have been chosen considering the following proposed experiments: [10, 19] (NFG), [14, 15] (NFS), [20] (SB) and [12] (BB). For the different beams we have taken as representative the CERN Neutrino Factory, SPL and BetaBeam proposals.\(^4\)

The input parameters used in the computation are:

• The Atmospheric Sector: \( \Delta m^2_{23} = 2.5 \times 10^{-3} \text{eV}^2 \), \( \theta_{23} = 40^\circ \);

• The Solar Sector: \( \Delta m^2_{12} = 7.3 \times 10^{-5} \text{eV}^2 \), \( \theta_{12} = 35^\circ \);

• The Matter Parameter: \( A = 1.1 \times 10^{-4} \text{eV}^2/\text{GeV} \).

In Sect. 4.1 we compare the clone locations derived from equiprobability and ENE curves; in Sect. 4.2 we consider the intrinsic and the sign clones; in Sect. 4.3 we focus on the octant and the mixed clones. We have shown in Sect. 3.2 that the two pairs of solutions are indeed related in the vacuum limit.

## 4.1 Equiprobability flow vs ENE flow

From a theoretical point of view one can look at the clone displacement with respect to the true solution \( (\theta_{13} = \bar{\theta}_{13}, \delta = \bar{\delta}) \) solving either the systems for the equiprobability curves, eqs. (5-8), or the corresponding systems for the ENE curves, eqs. (17-20). One should expect the two treatments to be equivalent: this is not always the case.

In Fig. 1 we plot the location of the intrinsic clone that results from the equiprobability curves and from the ENE curves. These points graphically depict how far from the true solution the degeneracy falls. A small change in the input parameter \( \bar{\theta}_{13} \) results in a small shift of the clone location (remind, however, the \( 2\pi \)-periodicity in the \( \delta \) axis). Almost continuous geometrical regions where degeneracies lie are therefore defined for a given interval in \( \bar{\theta}_{13} \), illustrating how the clones move due to a change in the input parameters: we will call this the “clone flow”. In the left plot we present the results for the Neutrino

\(^4\)See for example in [21] for a detailed description of each of these proposals.
Figure 1: *Intrinsic clone flow for the Neutrino Factory golden and silver channels (left) and the SuperBeam and BetaBeam signals (right), in the $(\Delta \theta_{13}, \delta)$ plane for $\bar{\theta}_{13} \in [0.1^\circ, 10^\circ], \bar{\delta} = 90^\circ$. The full circle is the true solution. The full (empty) symbols represent the intrinsic clone flow, computed from the ENE (equiprobability) curves.*

Factory-based golden and silver channels (i.e. $\nu_e \to \nu_\mu, \nu_\tau$), whereas in the right plot those of a SuperBeam-based $\nu_\mu \to \nu_e$ and of a BetaBeam-based $\nu_e \to \nu_\mu$ signals. The clone locations have been computed for variable input parameter $\bar{\theta}_{13}$ in the range $\bar{\theta}_{13} \in [0.1^\circ, 10^\circ]$ and fixed $\bar{\delta} = 90^\circ$. The arrows describe the direction of the flows: from large to small $\bar{\theta}_{13}$. The plots should be read as follows:

- the horizontal axis is $\Delta \theta_{13} = \theta_{13} - \bar{\theta}_{13}$. This is the value of the $\theta_{13}$-shift, as derived in the second solution of eq. (27);

- the vertical axis is the CP-violating phase $\delta$ itself, as it can be derived introducing the result of eq. (27) into one of eqs. (25).

For any value of the input parameter $\bar{\theta}_{13}$ the true solution is represented by the full (black) circle in $\Delta \theta_{13} = 0, \delta = \bar{\delta} = 90^\circ$. Notice that this property is specific to the intrinsic case. In general, both solutions of eqs. (18)-(20) will differ from the true solution $(\bar{\theta}_{13}, \bar{\delta})$. The intrinsic clones, computed using the ENE or the equiprobability equations, are respectively plotted as full or empty symbols as explained in the legend and in the caption.

In the left plot of Fig. 1 we can clearly identify the golden and silver channel intrinsic clone flow\(^5\). The NFG flow goes from the true solution toward positive $\Delta \theta_{13}$ and positive

\(^5\)For this specific plot we are choosing the energy bin between 30-40 GeV but the same conclusion
\[ \delta - \bar{\delta} : \text{for } \bar{\theta}_{13} = 10^\circ \text{ we have } \Delta \theta_{13} \sim 0.5^\circ \text{ and for very small } \bar{\theta}_{13}, \Delta \theta_{13} \rightarrow 1.5^\circ. \] The NFS flow goes from negative \( \Delta \theta_{13} \) and positive \( \delta - \bar{\delta} \) toward positive \( \Delta \theta_{13} \) and negative \( \delta - \bar{\delta} \). The different behavior of the two flows reflects the results of eq. (27). For \( \nu_e \rightarrow \nu_\mu \) transitions, the second solution of eq. (27) gives \( \sin^2 2\bar{\theta}_{13} \geq \sin^2 2\bar{\theta}_{13} \) for any value of \( \bar{\theta}_{13} \), being \( C \) and \( D \) strictly positive quantities. On the contrary, due to the formal replacement of the convolution integrals \( I_2^\mu \rightarrow -I_2^\tau, I_3^\mu \rightarrow -I_3^\tau \) we find that \( C^\tau, D^\tau \) are strictly negative quantities. For changing \( \bar{\theta}_{13} \), therefore, the \( \theta_{13} \)-shift can either be positive or negative. Notice how the intrinsic flows computed from the integrated ENE curves and from the equiprobability curves (almost) coincide for the Neutrino Factory-based samples.

In the right plot of Fig. 1 SuperBeam and BetaBeam-based flows are shown. The ENE clone flow for the SB facility (full diamonds) has a very small \( \Delta \theta_{13} \) (\( \leq 0.1^\circ \)) and it is practically insensitive to the change of \( \bar{\theta}_{13} \). The shift in \( \delta - \bar{\delta} \) is always negative and become smaller for larger \( \bar{\theta}_{13} \). The ENE clone flow for the BB facility (full squares) is practically identical to the SB one. This means that the presence of the intrinsic clone in these two facilities does not interfere with the measure of \( \theta_{13} \), whereas can drastically reduce the ability of measuring the CP phase.

The important feature is that for all these facilities the difference between using ENE (full symbols) or equiprobability (empty symbols) curves is quite substantial. Using theoretical information from the equiprobability curves could lead to largely wrong conjectures, in particular regarding the \( \bar{\theta}_{13} \) dependence that is practically absent in the ENE case and is conversely quite large using the equiprobability curves. The reason why SB and BB present this large difference between the two treatments has to be searched in their quite narrow energy spectrum. For very peaked spectra the approximation of “constant flux”, that is implicit in the equiprobability curves, badly fails. On the other hand, the broad neutrino spectrum from a Neutrino Factory makes the two treatments practically equivalent.

The theoretical results obtained for the intrinsic clone are quite general: a large difference in computing the clone location from ENE or equiprobability curves is observed for narrow band beam experiments, whereas no difference is observed for broad band beam experiments. For this reason, in the following sections we will compute the clone location for the different experiments using the integrated ENE curves.

### 4.2 The Intrinsic and the Sign Clone Flow

We now look for the different combinations of proposed facilities that help in solving the eightfold-degeneracy. The theoretical requirement for solving ambiguities is to find a specific combination of experiments such that the corresponding clone flows lie “well apart”. In this scenario an experimental fit to the data will result in a good \( \chi^2 \) absolute minimum near the true solution, where the information from different experiments adds coherently. Near the theoretical clone locations poor \( \chi^2 \) relative minima will be found, holds for all the other bins as well for the integrated flux.
Figure 2: Clone location in the \((\Delta \theta_{13}, \delta)\) plane for the intrinsic and sign degeneracies: BB (boxes); SB (diamonds); NFG (stars) and NFS (triangles). The full circle is the true solution, \(\Delta \theta_{13} = 0, \delta = 90^\circ\). Pictures (a) and (b) represent the intrinsic and sign clone flows for \(\tilde{\theta}_{13} \in [0.1^\circ, 10^\circ]\) and fixed \(\bar{\delta}\). Pictures (c) and (d) represent the intrinsic and sign clone location for \(\bar{\theta}_{13} = 1^\circ\).

since in these points the results of different experiments do not add coherently. In Fig. 2 we present the clone flow for the intrinsic (left) and the sign (right) degeneracies. The clone locations have been computed for variable input parameter \(\bar{\theta}_{13}\) in the range \(\tilde{\theta}_{13} \in [0.1^\circ, 10^\circ]\) and fixed \(\bar{\delta} = 90^\circ\) (upper plots) or for a fixed value, \(\bar{\theta}_{13} = 1^\circ, \bar{\delta} = 90^\circ\) (lower plots). Again the arrows indicate the direction of the flows from large to small \(\bar{\theta}_{13}\). In each figure the
results for the four facilities are presented together, in order to show how the combination of two or more of them can help solving that specific degeneracy. We illustrate the outcome of our analysis by studying the two degenerations one by one.

- **The Intrinsic Clone**: Fig. 2a, 2c.

The SB and BB intrinsic clone flows are extremely similar. This has already been noticed in the previous section, and is the result of the beam design. In [12] has been proposed to run the SPL and the BetaBeam at the same time and using the same detector located at \( L = 130 \text{ Km} \). In view of solving the degeneracies, this is clearly not a good option since the two flows always lie very near. The combination of these two facilities will still be affected by the intrinsic ambiguity.

This is not the case for the Neutrino Factory setup: the NFG channel is well separated from the NFS channel for any value of \( \bar{\theta}_{13} \). The golden channel combined with the silver and/or the SB/BB facilities is always, in principle, capable to solve the intrinsic ambiguity (i.e. provided that the corresponding experimental samples are all statistically significant and that systematic errors under control).

In Fig. 2c, we plot the intrinsic clone location for the small value \( \bar{\theta}_{13} = 1^\circ \), on the verge of the sensitivity limit.

- **The Sign Clone**: Fig. 2b, 2d.

It can be seen that again the SB and BB flows lie very near. A combination of them is therefore not suited to solve the sign degeneracy. On the other hand the Golden and Silver Neutrino Factory flows are quite separated. There could be some superposition between all the four flows for certain values of \( \bar{\theta}_{13} \) (e.g. NFG and NFS flows in the limit of vanishing \( \bar{\theta}_{13} \)). Nevertheless this superposition occurs in a region nearby the true solution where the existence of a clone is somewhat irrelevant.

The combination of either NFG or NFS with the SB or the BB signals should easily solve the ambiguity. In Fig. 2d, we plot the sign clone location for \( \bar{\theta}_{13} = 1^\circ \). Notice that for this specific case no NFG clones were found. This can be interpreted as a consequence of the very good (theoretical) sensitivity to matter effects (i.e. the \( \Delta m^2_{23} \) sign) of the NFG for \( L = 2810 \text{ Km} \). Be aware, however, that in a realistic experimental case a sign clone could appear also for the NFG due to statistical and systematical uncertainties.

As a final comment notice that the results for the sign clone for the SB and BB flows are in perfect agreement with the theoretical analysis of Sect. 3.2. For these two facilities the vacuum limit can be considered a good approximation (being \( L = 130 \text{ Km} \)) and we therefore expect the same \( \Delta \theta_{13} \) shift as in the intrinsic case with \( \delta_{\text{sign}} = \pi - \delta_{\text{int}} \). This is indeed the case by looking at Fig. 2a and Fig. 2b.

\(^6\) Notice, however, that for large \( \bar{\theta}_{13} \) angles even the Golden channel alone can solve the sign ambiguity being strongly sensitive to matter effects.
Figure 3: Clone location in the $(\Delta \theta_{13}, \delta)$ plane for the octant and mixed degeneracies: BB (boxes); SB (diamonds); NFG (stars) and NFS (triangles). The full circle is the true solution, $\Delta \theta_{13} = 0$, $\delta = 90^\circ$. Pictures (a) and (b) represent the octant and mixed clone flows for $\bar{\theta}_{13} \in [0.1^\circ, 10^\circ]$ and fixed $\bar{\delta}$. Pictures (c) and (d) represent the octant and mixed clone location for $\bar{\theta}_{13} = 1^\circ$. The results have been computed with $\theta_{23} = 40^\circ$. 
4.3 The Octant and the Mixed Clones

If $\theta_{23}$ was maximal no additional degeneracies were present. Otherwise two further degeneracies do appear\(^7\). In Fig. 3 we present the clone flow for the octant (left) and the mixed (right) degeneracies. The clone locations have been computed for variable input parameter $\hat{\theta}_{13}$ in the range $\hat{\theta}_{13} \in [0.1^\circ, 10^\circ]$ and fixed $\hat{\delta} = 90^\circ$ (upper plot) or for a fixed value, $\hat{\theta}_{13} = 1^\circ, \hat{\delta} = 90^\circ$ (lower plots). In each figure the results for the four facilities are presented together.

In Figs. 3a and 3b a very complicated pattern of clone flows appears. For this reason we discuss the specific case of $\hat{\theta}_{13} = 1^\circ$ depicted in Figs. 3c and 3d.

- **The Mixed Clone**: Fig. 3b/3d.

  We again notice that BB (boxes) and SB (diamonds) clones lie very near. As in the case of the sign ambiguity, no NFG mixed clones appear for this specific $\hat{\theta}_{13}$. Finally, the NFS clones are well separated from the BB/SB pairs. The combination of the golden and/or the silver channel and one of the BB/SB facilities can, in principle, solve the mixed degeneracy.

- **The Octant Clone**: Fig. 3a/3c.

  This is certainly the most difficult degeneracy to solve, since the flows of the four facilities overlap in a significant region of the $(\Delta \theta_{13}, \delta)$ plane, Fig. 3a. It seems feasible to reduce the overall ambiguity by combining NFG and NFS or BB/SB facilities, as it can be seen in Fig. 3c. A complete elimination of this degeneracy can perhaps be achieved combining the NFG, NFS and one of the BB/SB experiments.

5 Conclusions

In this paper we derive the theoretical location of the so-called “clones” that appear in the simultaneous measurement of $\theta_{13}$ and $\delta$. The general technique used to write analytical formulae for the clone location for the four degeneracies (called *intrinsic*, *sign*, *octant* and *mixed*) has been reported. Our analytical results apply to equiprobability and equal-number-of-events (ENE) curves as well. However, we have shown that the clone location computed from equiprobability or ENE curves can differ significantly for narrow band beam experiments. Notice that the latter approach reproduces the experimental situation, where the signal is represented by charged leptons in the detector and not by the oscillation probability itself. Using theoretical information from the equiprobability curves could thus lead to largely wrong conjectures. In the actual calculation we have therefore presented results obtained using the ENE curves.

\(^7\)Be aware that these clones will appear also for maximal $\theta_{23}$ once including the unavoidable experimental error band.
We present the clone flow for experiments fuelled by three different beams, using as a reference the CERN proposal for a SuperBeam, a BetaBeam and a Neutrino Factory. In the case of the Neutrino Factory two different detectors have been considered to take care of the “golden” and “silver” channel.

Our results show that the combination of these specific SuperBeam and BetaBeam does not help in solving any of the degeneracies. All the clone solutions for these two facilities lie very near, as a consequence of the fact that they have a very similar energy spectrum and that both are using the same detector located at $L = 130$ Km.

The combination of the Neutrino Factory golden and silver channel, on the contrary, seems to help significantly to reduce ambiguities. In our theoretical analysis, indeed, the intrinsic, sign and mixed clone flows for NFG and NFS lie well apart for $\bar{\theta}_{13} \geq 1^\circ$. As a general comment, we deduce that the combination of the NF golden channel with either the NF silver channel or with one of the pair BB/SB could in principle solve these three ambiguities.

This is not the case for the octant clones. Although a significant reduction of the degeneracy can be attained combining the NFG with the NFS or with one of BB/SB, it seems that a complete elimination of the octant clones can be achieved only by combining the three facilities, NFG, NFS and BB/SB. Nevertheless, even using the combination of all the available facilities is quite possible that the experimental uncertainties will not permit to solve completely the octant ambiguity for small values of $\bar{\theta}_{13}$. The ultimate sensitivity of the future neutrino experiments to $\delta$ is therefore strongly dependent on the success or failure in solving it. To decouple the pair BB/SB (e.g. using the Minos OA proposal \cite{22} for a SuperBeam) can probably be of great help in solving the octant clone.

**A The Analytic Clone Location in Matter**

In this appendix we generalize the treatment given for the intrinsic clone in Sect. 3.1 to a generic case where the discrete variables $s_{atm}$ and $s_{oct}$ can assume different values between left and right hand side of eqs. (17)-(20).

Using eq. (35) and eq. (36) we get:

$$\sin \delta = \frac{C'_1 \sin^2 2\theta_{13} - C'_1 \sin^2 2\bar{\theta}_{13}}{\cos \bar{\theta}_{13} \sin 2\theta_{13}} + \left[ C'_2 \cos \bar{\delta} + D'_3 \sin \bar{\delta} \right] g(\theta_{13}, \bar{\theta}_{13}) + C'_4 h'(\theta_{13})$$
where, using a notation as much resembling as possible that of the intrinsic case, we have defined the following coefficients:

\[
\begin{align*}
C_1' &= \frac{[I_1^+ I_2^- - I_1^- I_2^+]}{I_3^+ I_2^- + I_3^- I_2^+} \\
C_2' &= \frac{[I_2^+ I_2^- - I_2^- I_2^+]}{I_3^+ I_2^- + I_3^- I_2^+} \\
C_3' &= \frac{[I_3^+ I_3^- - I_3^- I_3^+]}{I_3^+ I_3^- + I_3^+ I_3^-} \\
C_4' &= \frac{[I_4(I_2^- - I_2^+)]}{I_3^+ I_2^- + I_3^- I_2^+} \\
D_1' &= \frac{[I_1^+ I_3^+ + I_1^- I_3^-]}{I_3^+ I_2^- + I_3^- I_2^+} \\
D_2' &= \frac{[I_2^+ I_3^+ + I_2^- I_3^-]}{I_3^+ I_2^- + I_3^- I_2^+} \\
D_3' &= \frac{[I_3^+ I_3^+ + I_3^- I_3^-]}{I_3^+ I_2^- + I_3^- I_2^+} \\
D_4' &= \frac{I_4(I_3^- I_3^+)}{I_3^+ I_2^- + I_3^- I_2^+} 
\end{align*}
\]

Notice that in vacuum all the coefficients of the \( C \)-type vanish. Using the discrete transformation properties of the integrals \( I_j \) of Tab. 1 we derive the corresponding transformation properties for the \( C_i \) and \( D_i \) coefficients, reported in Tab. 2. The \( \theta_{23} \)-octant transformation does not affect any of the \( C'_i \) or \( D'_i \) coefficients, but only \( C_1 \) and \( D_1 \) that are multiplied by \( \cot^2 \theta_{23} \) when \( \theta_{23} \to \pi/2 - \theta_{23} \). The effect of an \( s_{\text{atm}} \) change is much stronger: all coefficients are affected by this change. The \( C_i' \) and \( D_i' \) coefficients are obtained by the \( C'_{1,2,3}, D'_{1,2,3} \) in eq. (47) by changing \( I_2^\pm \to -I_2^\mp \) and \( I_3^\pm \to I_3^\mp \).

We present hereafter the explicit analytic solution for the \( \theta_{13} \)-shift for the octant and sign clones. Inserting these results in one of eqs. (46) the \( \delta \)-shift can be extracted. We do not present here the corresponding expression for the mixed clone.

### A.1 The Octant Clone

Using Tab. 2 we get for the \( \theta_{13} \)-shift for the octant clone the following expression:

\[
\sin^2 2\theta_{13} = \sin^2 2\bar{\theta}_{13} + \frac{\tan^2 \theta_{23}}{C_1'^2 + D_1'^2} \left[ (C_1 \sin \bar{\delta} + D_1 \cos \bar{\delta}) \sin 2\bar{\theta}_{13} + \frac{1}{2} \tan^2 \theta_{23} \right] - (1 - \tan^2 \theta_{23}) \left[ \sin^2 2\bar{\theta}_{13} - \tan^2 \theta_{23} \frac{C_1 C_4 + D_1 D_4}{C_1'^2 + D_1'^2} \right] \]

\[(48)\]
A.2 The Sign Clone

Using Tab. 2 we get for the $\theta_{13}$-shift for the sign clone the following expression:

\[
\sin^2 2\theta_{13} = - \left( \frac{\bar{C}_4 \bar{C}_4 + \bar{D}_4 \bar{D}_4}{\bar{C}_4^2 + \bar{D}_4^2} \right) \sin^2 2\bar{\theta}_{13}
\]

\[
+ \frac{1}{2 \left( \bar{C}_4^2 + \bar{D}_4^2 \right)} \left[ 1 - 2 \left( \bar{C}_4 \bar{C}_4 + \bar{D}_4 \bar{D}_4 \right) \cos \delta \sin 2\bar{\theta}_{13} - 2 \left( \bar{C}_4 \bar{C}_4 + \bar{D}_4 \bar{D}_4 \right) \sin \delta \sin 2\bar{\theta}_{13} \right]
\]

\[
\pm \frac{1}{2 \left( \bar{C}_4^2 + \bar{D}_4^2 \right)} \left\{ \left[ 1 - 4 \left( \bar{C}_4 \bar{C}_4 + \bar{D}_4 \bar{D}_4 \right) \cos \delta \sin 2\bar{\theta}_{13} + 4 \left( \bar{C}_4 \bar{C}_4 + \bar{D}_4 \bar{D}_4 \right)^2 \cos^2 \delta \sin^2 2\bar{\theta}_{13} \right] \right\}
\]

It can be easily shown that in the vacuum limit, when $C_1, C'_1 \rightarrow 0$, this equation reduces to the vacuum solution, eq. (40). Moreover, for $\theta_{23} \rightarrow 45^\circ$ reduces to the general solution in matter, eq. (27), for the intrinsic clone.
\[ -4 \left[ (\bar{C}_1 \bar{C}_3' + \bar{D}_1 \bar{D}_3')^2 + (\bar{C}_1' \bar{C}_1 + \bar{D}_1 \bar{D}_1') \right] \sin^2 2\bar{\theta}_{13} \\
-4 \left( \bar{C}_1 \bar{D}_1' - \bar{D}_1 \bar{C}_1' \right)^2 \sin^4 2\bar{\theta}_{13} \\
-8 \left( \bar{C}_1 \bar{D}_1' - \bar{D}_1 \bar{C}_1' \right) \left[ \left( \bar{C}_1 \bar{C}_3' - \bar{D}_1 \bar{D}_3' \right) \cos \delta + \left( \bar{C}_1' \bar{C}_1 + \bar{D}_1 \bar{D}_1' \right) \sin \delta \right] \sin^3 2\bar{\theta}_{13} \\
-4 \left( \bar{C}_1 \bar{D}_2' + \bar{D}_1 \bar{C}_2' \right)^2 \cos^2 \delta \sin^2 2\bar{\theta}_{13} \\
-8 \left( \bar{C}_1 \bar{D}_2' - \bar{D}_1 \bar{C}_2' \right) \left( \bar{C}_1 \bar{C}_3' - \bar{D}_1 \bar{D}_3' \right) \sin \delta \cos \sin^2 2\bar{\theta}_{13} \\
-4 \left( \bar{C}_1 \bar{D}_3' + \bar{D}_1 \bar{C}_3' \right) \sin \delta \sin 2\bar{\theta}_{13} \right]^{1/2} \\
\]

One can verify that eq. (49) reduces to the vacuum solution, eq. (39). The first term in the square root goes to a perfect square; the second vanishes for an exact cancellation between $(\bar{D}_1 \bar{D}_3')^2$ and $\bar{D}_1 \bar{D}_1'$, since in vacuum $\bar{D}_1' \rightarrow -\bar{D}_1$, $\bar{D}_2' \rightarrow -1$ and $\bar{D}_3' \rightarrow 1$. All other terms in the square root trivially vanish since are multiplied by some $C$-type coefficient that goes to zero in the vacuum limit.
