Abstract

Purpose Positive mental health involves theoretical constructs like psychological well-being, personal meaning, and posttraumatic growth. This study aims to provide empirical insight into possible overlap between these constructs in cancer survivors.

Methods Within the context of a randomized controlled trial, 170 cancer survivors completed the patient-reported outcome measures (PROMs) Ryff’s Scales of Psychological Well-Being (SPWB), Personal Meaning Profile (PMP), and Posttraumatic Growth Inventory (PTGI). Exploratory factor analysis (EFA) on the subscales of these PROMs, as well as structural equation modeling (SEM), was used to explore overlap in these three constructs.

Results The EFA resulted in a three-factor solution with an insufficient model fit. SEM led to a model with a high estimated correlation (0.87) between SPWB and PMP and lower estimated correlations with PTGI (respectively 0.38 and 0.47). Furthermore, the estimated correlation between the subscales relation with God (PMP) and spiritual change (PTGI) was high (0.92). This model had adequate fit indices ($\chi^2(93) = 144, p = .001$, RMSEA = 0.059, CFI = 0.965, TLI = 0.955, SRMR = 0.061).

Conclusions The constructs psychological well-being and personal meaning overlap to a large extent in cancer survivors. Posttraumatic growth can be seen as a separate construct, as well as religiosity. These findings facilitate researchers to select the appropriate PROM(s) when testing the effect of a psychosocial intervention on positive mental health in cancer survivors.

Relevance An increasing number of psychosocial intervention trials for cancer survivors use positive mental health outcomes. These constructs are often multifaceted and overlapping. Knowledge of this overlap is important in designing trials, in order to avoid the pitfalls of multiple testing and finding artificially strengthened associations.

Background

Patient-reported outcome measures (PROMs) in psychosocial intervention trials targeting cancer survivors generally focus on psychological distress and quality of life [1]. However, absence of distress does not necessarily lead to positive mental health [2, 3]. Positive mental health involves factors such as psychological well-being [4], experiencing a sense of meaning in life [5], posttraumatic growth [6], self-compassion [7], and flourishing [8]. Evidence on the importance of positive mental health for a successful adjustment to life after cancer is growing [9–11]. Studies show that positive mental health protects cancer survivors against distress and demoralization [12] and that it plays a role in mental recovery after the treatment phase [13].

In the field of positive mental health research, constructs are often not clearly demarcated from each other, which can be
were recently used in a randomized controlled trial (RCT) on the efficacy of meaning-centered group psychotherapy (MCGP) for cancer survivors [26]. All three measurement instruments contain a subscale on relations with other people. Overlap between these measurement instruments is displayed in Table 1.

As a result of the overlap between these instruments, it is difficult to gain insight into what exactly is affected by interventions that aim to improve positive mental health. Furthermore, the question rises which (sub)scales of instruments are suited best to be used as primary outcome measure in RCTs investigating these interventions. Therefore, the aim of the present study was to investigate empirically the overlap between measurement instruments of psychological well-being and meaning in all its facets, including growth, finding new possibilities in life, and spirituality. An overview of the overlap between these measurement instruments is displayed in Table 1.

As a result of the overlap between these instruments, it is difficult to gain insight into what exactly is affected by interventions that aim to improve positive mental health. Furthermore, the question rises which (sub)scales of instruments are suited best to be used as primary outcome measure in RCTs investigating these interventions. Therefore, the aim of the present study was to investigate empirically the overlap between measurement instruments of psychological well-being, personal meaning, and posttraumatic growth among cancer survivors. Factor analysis was conducted on the subscales of the Dutch version of these well-validated PROMs (i.e., SPWB, PMP, and PTGI), as filled out in the context of the RCT evaluating MCGP [26]. It was presumed that factor analysis would not result in three separate factors representing psychological well-being, personal meaning, and posttraumatic growth. It was expected that a different factor structure would appear, crossing through these measurement instruments and revealing areas of overlap. The results will contribute to better understanding of the overlap of these positive mental health constructs, which is highly needed to develop core outcome sets to measure cancer survivors’ positive mental health in the future.

### Methods

#### Patients

For this study, baseline data were used from an RCT on the efficacy of MCGP for cancer survivors [26]. Ethical approval for this study was provided by the Medical Ethical Committee of Leiden University Medical Center (NL34814.058.10). Information about the study protocol, participants, and primary outcomes has been published previously [26, 27].

Participants were recruited between August 2012 and September 2014. Inclusion criteria were as follows: cancer diagnosis in the last 5 years, treated with curative intent, main treatment completed (i.e., surgery, radiotherapy, chemotherapy), presence of an expressed need for psychological support, and at least one psychosocial complaint. Exclusion criteria were as follows: severe cognitive impairment, current psychological or psychiatric treatment elsewhere, and an insufficient mastery of the Dutch language. All criteria were ascertained during a telephonic screening interview.

Informed consent was obtained from all individual participants included in the study. Demographic characteristics were obtained by self-report: age, gender, marital status, education level, employment, religious background, other negative life events, and past psychological treatment. Illness-related characteristics included type of cancer, tumor stage, type of treatment, and time since treatment and were retrieved from medical records or by self-report, if medical records were unavailable.

#### Outcome measures

Psychological well-being was measured using the Dutch version of the SPWB [28]. This is a 39-item measure consisting of six subscales: self-acceptance ($\alpha = 0.81$), positive relations with others ($\alpha = 0.83$), autonomy ($\alpha = 0.84$), environmental mastery ($\alpha = 0.76$), purpose in life ($\alpha = 0.79$), and personal growth ($\alpha = 0.071$). Items were answered on a 6-point Likert scale, ranging from 1 (strongly disagree) to 6 (strongly agree). Subscale scores were calculated as the mean item score. Higher scores indicated greater well-being. The Dutch version has the same six subscales as the original version, although several items had to be removed to reach adequate fit. The Dutch version showed sufficient internal consistency and good construct validity [28].
The Dutch version of the PMP was used to measure personal meaning [17, 29]. This 39-item measure has five subscales: dedication to life ($\alpha = 0.89$), fairness of life ($\alpha = 0.77$), goal-orientedness ($\alpha = 0.89$), relations with other people ($\alpha = 0.85$), and relation with God ($\alpha = 0.86$). Items were scored on a 7-point Likert scale from 1 (not at all) to 7 (a great deal). A higher score reflects a more important source of meaning. This measure was validated in Dutch cancer patients and showed good internal consistency and construct validity. Its number of items and factor structure differed from...
the original Canadian version. Of the originally 57 items, 18 had to be removed in the Dutch version, because of low or double loadings and the original factors “relations” and “intimacy” formed one factor in the Dutch version, as well as “fair treatment” and “self-acceptance” [29].

Posttraumatic growth was measured using the Dutch translation of the PTGI [25, 30]. This 21-item measure has five subscales: relating to others (α = 0.85), new possibilities (α = 0.80), personal strength (α = 0.79), spiritual change (α = 0.70), and appreciation of life (α = 0.75). Items were rated from 0 (not at all) to 5 (very great degree). Subscale scores were calculated as mean item scores and a higher score suggests stronger growth. A psychometric study of the PTGI in Dutch cancer patients showed good internal consistency, construct validity, and factorial validity. The Dutch version contains the same factors as the original version [30].

### Statistical methods

Exploratory maximum likelihood factor analysis (EFA) with varimax rotation on all subscales of the SPWB, PMP, and PTGI was conducted to explore possible areas of overlap between psychological well-being, personal meaning, and posttraumatic growth. The number of factors to retain was based on the eigenvalues (> 1.0), the slope of the scree plot and parallel analysis. To assess the goodness-of-fit of the resulting model, this model was entered into a confirmatory maximum likelihood factor analysis (CFA) using the same sample. The following goodness-of-fit indices and thresholds were used: the χ²-test (p < 0.05), the root mean square error of approximation (RMSEA, < 0.06), the comparative fit index (CFI, ≥ 0.90), the Tucker-Lewis index (TLI, ≥ 0.90), and the standardized root mean square (SRMS, < 0.08). Missing data were presumed to be missing completely at random (MCAR).

When the model resulting from the EFA would not show adequate fit, two additional models would be considered. (1) In order to compare the result of the EFA with the null model (i.e., a model in which the subscales load on a factor that represents their own measurement instrument, revealing no areas of overlap), the goodness-of-fit indices would be calculated for this null model, as well, using CFA. (2) In order to explore the overlap between the SPWB, PMP, and PTGI further, structural equation modeling (SEM) would be used. Beginning with the null model, in which each measurement instrument formed a latent variable, represented by its subscales as manifest variables, the path with the highest modification index would be added to the model and the goodness-of-fit indices would be re-calculated. This procedure would be repeated until the model had an adequate fit. Correlations in the models were considered as low (< 0.5), moderate (≥ 0.5 and < 0.7), or high (≥ 0.7). All analyses were performed in IBM SPSS Statistics 24 or R 3.4.0, package Lavaan.

### Results

#### Participant characteristics

In total, 2192 cancer survivors received an invitation letter for this study, 419 survivors responded positively, 184 met all inclusion criteria, and 170 completed the outcome measures at baseline. Participants were on average 57 years old and 82% was female. Eighty percent was married or in a relationship.

| Table 2  | Participant characteristics (N = 170) |
|----------|-------------------------------------|
|          | N  | %  | M  | SD | Median | Range   |

*a N = 165  
b N = 159  
c N = 168*
39% was higher educated, and 53% was employed. Breast cancer was diagnosed in 66% of the participants; 70% had tumor stage II or lower. All participants but one had surgery and 81% had additional radiation or chemotherapy. Participants were median 18 months post treatment. Other negative life events were reported by 53% of the participants, and 18% had psychological treatment in the last year (Table 2). More details on the participant flow and dropout can be found elsewhere [26].

**Exploratory factor analysis**

Based on the scree plot and the eigenvalues, three factors should be extracted. The parallel analysis, however, indicated a solution of two factors. The eigenvalue of the third factor (1.355) was below the parallel analysis eigenvalue at the 95th percentile (1.420). However, it was higher than the average parallel analysis eigenvalue of the third factor (1.347). Because both the scree plot and the eigenvalues indicated a three-factor solution, and the parallel analysis “almost” indicated a three-factor solution, this solution was retained (Table 3; see Online Resources 1 and 2 for descriptive statistics of the PROMs and a graphical representation of these factors). The three-factor solution explained 59% of the variance. The first factor consisted of all SPWB and PMP subscales, except the PMP subscale relation with God. The second factor consisted of all PTGI subscales, except spiritual change. The third factor consisted of the subscales relation with God (PMP) and spiritual change (PTGI). The goodness-of-fit indices of this three-factor solution were unsatisfactory ($\chi^2(101) = 314, p < .001$, RMSEA = 0.115 (95% CI 0.100–0.129), CFI = 0.854, TLI = 0.827, SRMR = 0.085), meaning that the model did not fit well with the data.

**Additional analyses**

Since the above described three-factor solution did not have an adequate fit, the question arose whether a model in which each measurement instrument formed a separate factor (null model) would better fit with the data. The results of this CFA showed that the goodness-of-fit indices of the null model were slightly worse ($\chi^2(101) = 357, p < .001$, RMSEA = 0.126 (95% CI 0.112–0.140), CFI = 0.825, TLI = 0.792, SRMR = 0.094).

When pathways were subsequently added to the null model using SEM, based on the modification indices, the fit improved ($\chi^2(93) = 144, p = .001$, RMSEA = 0.059 (95% CI 0.039–0.077), CFI = 0.965, TLI = 0.955, SRMR = 0.061). In the resulting model, the latent variables SPWB and PMP had an estimated correlation of 0.87, SPWB and PTGI of 0.38, and PMP and PTGI of 0.47 (Fig. 1). Furthermore, a path was added between the subscales relation with God (PMP) and spiritual change (PTGI) and between spiritual change (PTGI) and personal growth (SPWB). The subscale positive relations with others (SPWB) formed paths with relations with other people (PMP), relating to others (PTGI), and personal growth (SPWB). The subscale personal growth (SPWB) also loaded on the PTGI. The subscale relation with God (PMP) loaded negatively on the SPWB, as well. Finally, a negative pathway had to be added between the SPWB subscales autonomy and purpose in life. Since the fit of this model was adequate, it was considered as the main outcome of this study.

**Conclusions**

The empirical baseline data of cancer survivors participating in an RCT supported the expectation that measurement instruments of psychological well-being, personal meaning, and posttraumatic growth do share areas of overlap. The resulting model was complex, but three main conclusions can be drawn. (1) The scores on psychological well-being (SPWB) and personal meaning (PMP) were highly correlated (as latent variables), which suggests that both PROMs measure similar or very closely related aspects of positive mental health. (2) Their estimated correlation with the posttraumatic growth measure (PTGI), as latent variable, was lower, suggesting that posttraumatic growth is a related, but distinct construct. (3) A high estimated correlation was found between the subscales relation with God (PMP) and spiritual change (PTGI), while their loadings on their respective measurement instruments deviated from the other subscale loadings. This supports the idea that religiosity is distinct from psychological well-being, personal meaning, and posttraumatic growth.

**Table 3** Rotated (varimax) component matrix

| Subscales                  | Measurement Instrument | Loadings |
|----------------------------|------------------------|----------|
|                            |                        | 1        | 2        | 3        |
| Self-acceptance            | SPWB                   | 0.85     |          |          |
| Purpose in life            | SPWB                   | 0.85     |          |          |
| Environmental mastery      | SPWB                   | 0.82     |          |          |
| Dedication to life         | PMP                    | 0.74     |          |          |
| Goal-orientedness          | PMP                    | 0.69     | 0.32     |          |
| Positive relations         | SPWB                   | 0.63     |          |          |
| Autonomy                   | SPWB                   | 0.61     |          |          |
| Fairness of life           | PMP                    | 0.61     |          |          |
| Relation with other people | PMP                    | 0.57     |          |          |
| Personal growth            | SPWB                   | 0.53     | 0.35     |          |
| Personal strength          | PTGI                   | 0.83     |          |          |
| Appreciation of life       | PTGI                   | 0.77     |          |          |
| New possibilities          | PTGI                   | 0.73     |          |          |
| Relating to others         | PTGI                   | 0.67     |          |          |
| Relation with God          | PMP                    | 0.98     |          |          |
| Spiritual change           | PTGI                   | 0.32     | 0.63     |          |

Factor loadings < 0.30 are suppressed

*N* = 161
These results have clear implications for the use of the SPWB, PMP, and PTGI in trials that investigate the effect of psychosocial interventions targeting cancer survivors. The overlap implies that if an intervention aims to improve both psychological well-being and personal meaning, in fact, the same phenomena or behaviors, feelings, cognitions, goals and convictions may have changed. Measuring these constructs separately means that these specific phenomena are measured double [33]. Previous studies showed similar results in the operationalization of spirituality and well-being [31, 32]. It may be more efficient and less burdensome for cancer survivors to measure these phenomena just once.

In addition, taking this overlap into account may help to avoid various pitfalls in designing a trial. The overlap between these measures will artificially increase the strength of their association [31], so one may wrongly conclude that personal meaning leads to psychological well-being or vice versa. Furthermore, measuring both constructs increases the problem of multiple testing, because the same phenomena are measured more often. Further psychometric research is needed to select those items from the SPWB and PMP that measure these overlapping phenomena in the most parsimonious way with the largest sensitivity for change.

The results of this study do not mean that psychological well-being and meaning are entirely exchangeable concepts. Their connotations are different [15], these concepts are rooted in different literary and research traditions, and their measures will not invariably give similar outcomes. What this study does show, however, is that when it comes to operationalization, these constructs overlap in many ways. Better insight into cancer survivors’ positive mental health is served by acknowledging this overlap.

Despite the conceptual overlap between posttraumatic growth, psychological well-being, and personal meaning, the results of this study suggest that mainly psychological well-being and personal meaning overlap, while posttraumatic growth falls farther outside. This is in agreement with several studies that did not find a significant association between posttraumatic growth and well-being [18, 34]. An alternative explanation for this outcome is that the PTGI requires a different type of item response than the SPWB and PMP. Survivors are not asked to rate how they feel at the moment, but how their feelings differ from before cancer. Scales with a different type of item response may artificially influence SEM results.

Finally, the results support the idea that religiosity can be seen as distinct from psychological well-being, personal meaning, and posttraumatic growth. Perhaps, especially in a secular country like The Netherlands, there is a large variability in the role religion plays in people’s lives, ranging from absent to prominent and from negative to positive. This finding is in line with previous studies in The Netherlands [28], as well as in the USA [35]. Hence, it seems that religiosity is a domain that should be measured separately in cancer survivors.

This study had several limitations. First, the number of participants was relatively small, females and breast cancer survivors were overrepresented, and all analyses were...
conducted using the same sample. Second, only three of the many available, albeit frequently used measures of well-being, meaning, and posttraumatic growth, were examined. It is possible that other measures show less overlap. Third, psychological well-being, personal meaning, and posttraumatic growth do not cover the full spectrum of positive mental health [16]. To identify the domains of a core outcome set for cancer survivors’ positive mental health, future studies should include a broader variety of measurement instruments [36]. Such a core outcome set of positive mental health in cancer survivors can be used routinely to document and compare effects of psychosocial intervention on survivors’ positive mental health.

The majority of cancer survivors have no clinical level of distress, but there is a large differentiation in their level of positive mental health [2]. Since a growing number of survivors will live for an increasing number of years [37], it becomes important that high-quality psychosocial interventions are available that stimulate positive mental health and help survivors adjust to the aftermath of cancer. The efficacy of interventions can only be evaluated when their effects can be monitored properly. This study contributes to the understanding of positive mental health in cancer survivors and to develop a core outcome set.

Conclusion

Psychological well-being and personal meaning overlap to a large extent in cancer survivors, while posttraumatic growth and religiosity can be seen as distinguished constructs. These findings facilitate researchers to select the appropriate PROMs when testing the effect of a psychosocial intervention on positive mental health in cancer survivors.
