Although the low frequency electronic Raman response in the superconducting state of the cuprates can be largely understood in terms of a d-wave energy gap, a long standing problem has been an explanation for the spectra observed in the $A_{1g}$ polarization orientations. We present calculations which suggest that the peak position of the observed $A_{1g}$ spectra is due to a collective spin fluctuation mode.

PACS numbers: 74.72.-h, 78.30.-j 71.10.-w

Electronic Raman scattering has proven to be a useful tool in exploring the superconducting state in the cuprate materials. The possibility of probing selectively electronic excitations in different regions of the Brillouin zone (BZ) by the choice of polarization geometries has allowed to explore the superconducting gap anisotropy. The successful explanation of the Raman data in $B_{1g}$ and $B_{2g}$ scattering geometries has provided one piece of evidence for the by now widely accepted $d_{x^2-y^2}$ pairing symmetry in hole-doped cuprate superconductors. In the context of impurity effects as a testing ground for unconventional superconductivity, the observed $\omega^3$ to $\omega$ crossover in the low frequency $B_{1g}$ Raman response fits consistently with the power law crossovers at low temperatures in the NMR relaxation rate and in the magnetic penetration depth. An even quantitatively consistent picture of electronic Raman scattering and infrared conductivity was achieved when the T-matrix approximation in the “dirty” d-wave scenario is extended to include a spatial extension of the impurity potential.

However up to now the discrepancy between Raman data in $A_{1g}$ and $B_{1g}, B_{2g}$ geometries has remained unresolved. Previous results for the $A_{1g}$ scattering geometry were found to be very sensitive to changes in the Raman vertex function $\gamma(k)$ making a comprehensive explanation difficult for the experimental data in different cuprate materials.

In this paper we calculate the Raman response of a $d_{x^2-y^2}$ superconductor including the contribution from a collective spin fluctuation (SF) mode which is identified with the $(\pi, \pi, \pi)$-resonance (in short $\pi$-resonance) near $\omega_R \approx 41$ meV observed by inelastic neutron scattering (INS) on bilayer cuprates. Our results suggest that the $A_{1g}$ peak position is largely controlled by the strength and frequency of the $\pi$-resonance mode which on the other hand does not affect the Raman response in the $B_{1g}$ and $B_{2g}$ channels. The inclusion of the collective SF mode allows for a simultaneous fit of the Raman data in all channels in optimally doped materials. Furthermore we find that the inclusion of the SF term significantly reduces the sensitivity to the special choice of the underlying tight-binding band structure, i.e. the sensitivity to the choice of the Raman vertex in $A_{1g}$ symmetry, resolving the previously encountered problems in the symmetry analysis of the light scattering amplitude.

On the basis of the observation of the collective SF mode in Y-123 and Bi-2212, we consider a bilayer model represented by a tight-binding band structure with an inter-plane hopping given by

$$\epsilon_k = -2t(\cos(k_x) + \cos(k_y)) + 4t' \cos(k_x) \cos(k_y) - t_\perp(k),$$

with an inter-plane hopping given by

$$t_\perp(k) = 2t_\perp \cos(k_x)(\cos(k_x) - \cos(k_y))^2$$

where $k_z$ is 0 or $\pi$ for the bonding or anti-bonding bands of the bilayer, respectively.

The spin susceptibility ($\chi_s$) is modeled by extending the weak coupling form of a BCS superconductor in a $d_{x^2-y^2}$ pairing state to include antiferromagnetic spin fluctuations by a RPA form with an effective interaction $\tilde{U}$; i.e. $\chi_s(q, i\omega) = \chi^0(q, i\omega)/(1 - U \chi^0(q, i\omega))$ where

$$\chi^0(q, i\omega) = \frac{1}{\beta} \text{Tr} \sum_{k, \omega'} \hat{G}(k, \omega')\hat{G}(k + q, \omega' + i\omega).$$

$\text{Tr}$ denotes the trace and $\beta = T^{-1}$. $\hat{G}(k, i\omega)$ is the BCS Green’s function in Nambu space

$$\hat{G}(k, i\omega) = \frac{i\omega \tilde{\tau}_0 + \xi_k \tilde{\tau}_3 + \Delta_k \tilde{\tau}_1}{(i\omega)^2 - \xi_k^2 - \Delta_k^2}$$

with $\tilde{\tau}_i$ (i=1,2,3) the Pauli matrices, $\tilde{\tau}_0$ the $2 \times 2$ unit matrix, $\xi_k = \epsilon_k - \mu$ and $\Delta_k = \Delta_0(\cos(k_x) - \cos(k_y))/2$. This form of the spin susceptibility contains a strong magnetic resonance peak at $q = Q \equiv (\pi, \pi, \pi)$ which was proposed to explain the INS resonance at energies near 41 meV in Y-123 and Bi-2212. Other forms for the spin susceptibility can be straightforwardly used within our model. However, the results are mainly determined by the collective mode at $Q$. Therefore we take the bilayer susceptibility for a representative calculation.

The intensity of scattered light $I(\omega)$ in Raman experiments is proportional to the imaginary part of the response function for the effective density operator.
in the long wavelength limit \( \mathbf{q} \to \mathbf{0} \). Specifically

\[
I(\Omega) \propto (1 + n(\Omega)) \text{Im} \chi(\Omega + i0^+) \\
\chi(i\Omega) = \int_0^{1/T} d\tau e^{-i\Omega\tau} \langle T_\tau [\hat{\rho}(\tau), \hat{\rho}(0)] \rangle, \tag{5}
\]

with the Bose function \( n(\omega) \) and the time ordering operator \( T_\tau \).

The bare Raman vertex \( \hat{\gamma}(\mathbf{k}) = \tau \gamma(\mathbf{k}) \) in different scattering geometries are classified according to the elements of the \( D^{th} \) point group. For the limiting case of vanishingly small scattered \((\omega_S)\) and incident \((\omega_I)\) photon energies, it can be represented in the effective-mass approximation (EMA)

\[
\gamma(\mathbf{k}) = \sum_{\alpha, \beta} e^{\ell}_\alpha \frac{\partial^2 \tilde{e}_k}{\partial k_\alpha \partial k_\beta} e^{S}_\beta \tag{6}
\]

where \( e^\ell \) and \( e^S \) are the unit vectors for in-plane polarizations (i.e. \( \alpha, \beta \in \{x, y\} \)) of the incoming and the scattered light, respectively. Using Eq. (6) and the bilayer tight-binding dispersion Eq. (4) we obtain

\[
\gamma^B_{\mathbf{k}^I\mathbf{k}^F} = 2t \tilde{\gamma}^S_k \left( 1 + \frac{4t}{\hbar} \cos(k_x) \cos(k_x) + \cos(k_y) \right) \tag{7}
\]

\[
\gamma^A_{\mathbf{k}^I\mathbf{k}^F} = 2t \tilde{\gamma}^d_k - 2t \cos(k_x) \cos(2k_x) + 2t \cos(k_y) - 4 \cos(k_x) \cos(k_y) \left[ \ell^I + 2t \cos(k_z) \right] \tag{8}
\]

where \( \gamma^d_k = \cos(k_x) + \cos(k_y) \)/2. However, the EMA has a questionable region of validity for all Raman measurements on the cuprates since the incoming photons have energy \( \sim 2\text{eV} \), which is on the order of the bandwidth and the inter-band excitations according to local density calculations. EMA based arguments in previous works about relative Raman intensities for different channels are therefore questionable. We hence consider other forms for the vertices as well which obey the proper symmetry transformations. For the \( A_{1g} \) geometry some symmetry compatible choices are \( \gamma(\mathbf{k}) = \cos(k_x) + \cos(k_y) \) and \( \gamma(\mathbf{k}) = \cos(k_x) \cos(k_y) \). These basis functions assign weight to different regions of the BZ and this is the reason why previous results for the \( A_{1g} \) response were particularly sensitive to the specific choice of the bare Raman coupling vertex.

The spin fluctuations lead to an additional contribution for the Raman response via a 2-magnon like process as shown diagrammatically in Fig. 1. Here, the SF propagator is incorporated in its RPA form for the bilayer (as described above) by the ladder diagram series with an effective on-site Hubbard interaction \( \tilde{U} \).

We therefore write the Raman response function at finite temperature as the sum of a pair-breaking (PB) and a SF contribution

\[
\chi_{\gamma\gamma}(\mathbf{q}, i\omega) = \chi_{\gamma\gamma}^{PB}(\mathbf{q}, i\omega) + \chi_{\gamma\gamma}^{SF}(\mathbf{q}, i\omega) \tag{9}
\]

\[
\chi_{\gamma\gamma}^{SF}(i\Omega) = \sum_{\mathbf{q}', \mathbf{i} \omega} V^\gamma(\mathbf{q}', i\Omega, i\omega) \chi_{\gamma}(\mathbf{q}', -\mathbf{q}', -i\omega) \times \chi_{\gamma}(\mathbf{q}', i\omega + i\Omega) V^\gamma(\mathbf{q}', -i\Omega, -i\omega). \tag{10}
\]

The vertex function \( V^\gamma(\mathbf{q}', i\Omega, i\omega) \) includes the bare Raman vertex and is evaluated as

\[
\chi_{\gamma\gamma}^{PB}(i\Omega) = \sum_{\mathbf{q}, \mathbf{k}, \mathbf{i} \omega, \mathbf{i} \omega'} V^\gamma(\mathbf{k}, i\omega') \tilde{G}(\mathbf{k}, \mathbf{i} \omega + i\Omega) \gamma(\mathbf{k}, i\omega'). \tag{12}
\]

The total Raman response is calculated in the gauge invariant form which results from taking into account the long wavelength fluctuations of the order parameter to guarantee local charge conservation. The total Raman susceptibility thus follows as

\[
\chi(i\Omega) = \chi_{\gamma\gamma}(i\Omega) - \chi_{\gamma\gamma}^{PB}(i\Omega) \chi_{\gamma\gamma}^{SF}(i\Omega). \tag{13}
\]

where \( \chi_{\gamma\gamma} \) and \( \chi_{\gamma\gamma}^{PB} \) are obtained by the replacement \( \gamma(\mathbf{k}) \to 1 \) in one or both bare Raman vertices in the
we have evaluated the Raman response at a temperature 0, while the gap has been chosen as \( \Delta_0 \). The analytical continuation to the real axis is performed using Padé approximants [13].

The band structure parameters are chosen for all geometries. The parameters used are defined in the text.

Let’s first consider \( \chi_{SF} \) alone. In Fig. 2 we plot \( \chi_{SF}'' \) for the \( A_{1g} \) channel versus frequency. \( \chi_{SF} \) is a convolution of two spin susceptibilities (Eq. (10)) and is thus peaked at an energy near twice the magnetic resonance energy. An important point is that in the \( B_{1g} \) and \( B_{2g} \) geometries the SF term introduces vanishingly small corrections to the total response, rendering the presence of the SF term important only in the \( A_{1g} \) geometry. This is due to the sharpness in momentum space of the resonance peak at \( \mathbf{Q} \) in the SF propagator. In fact, if the transfer is taken only at \( \mathbf{Q} \), both the \( B_{1g} \) and \( B_{2g} \) contributions to \( \chi_{SF} \) vanish identically, as can be seen from Eq. (11). Therefore for these channels the response is given by the PB term alone.

In Fig. 3 we illustrate the frequency dependence of \( \chi''(\Omega) \) in the \( A_{1g} \) geometry for three different values of the effective interaction with both the PB and SF contributions included. The shape of the Raman response is modified varying \( U/t \) and in particular the position of the resonance is shifted towards higher energies for increasing \( U \). With the inclusion of the SF term we now obtain a peak slightly above \( \Delta_0 \) as observed experimentally in Y-123 and Bi-2212.

A comment is in order on the relative magnitude of the SF and the PB term. Comparing Figs. 2 and 3 it is clear that the SF term is much smaller than the PB term, but the effect of this new term is nevertheless visible since the backflow (the second term in Eq. (13)) mixes in a non-trivial way the two contributions. Since the SF term varies as \( U^4 \) in our model it starts to dominate for larger \( U \), leading to a shift in spectral weight out towards \( 2\omega_R \), which also changes with \( U \).

The experimental position of the peak is not sample dependent in the \( A_{1g} \) geometry as already mentioned, and is almost the same in different cuprates. On the other hand the theoretical description with the PB term alone is very sensitive to Raman vertex changes, which can produce variation of its position between \( \Delta_0 \) and \( 2\Delta_0 \), not allowing for a comprehensive modeling of different cuprates.

In Fig. 4 we address the problem of the sensitivity of the result to changes in the bare Raman vertex \( \gamma(k) \). To investigate the effect of changes of the vertex function, we have calculated the final response using the three different forms for the vertex \( \gamma(k) = \cos(k_x) + \cos(k_y) \), \( \gamma(k) = \cos(k_x) \cos(k_y) \) and in the EMA which posses the correct transformation properties required by symmetry. In the first panel of Fig. 4 we have plotted the Raman response for \( U = 0 \), i.e. the PB contribution alone, and in the second panel for \( U/t = 1.3 \). All curves are renormalized to their peak height to allow for an easier comparison. Clearly the strong sensitivity to changes of the bare Raman vertex (first panel) is much reduced when the SF term is added (second panel).

In Fig. 5 we compare the theoretical results with experimental data on optimally doped Bi-2212 [4]. Adding the SF contribution leads to a shift of the peak position from near \( \Delta_0 \) for \( U = 0 \) to higher frequencies, and thus to a better agreement with the experimental relative peak positions in \( A_{1g} \) and \( B_{1g} \) geometries. For the fit we have adjusted \( t \) to achieve a good agreement with the \( B_{1g} \) channel, and then adjusted \( U \) to match the \( A_{1g} \) peak position.

The value of \( t \) obtained from the fit is \( t = 130 \) meV. This value has to be compared with \( t \approx 105 \) meV, which results from the condition \( \omega_R \approx 40 \) meV. This slight discrepancy is most probably related to our simple mod-
FIG. 4. The total $A_{1g}$ response for different vertices: $\gamma$ obtained from effective mass approximation (solid line), $\cos(k_x) + \cos(k_y)$ (dashed line), $\cos(k_x)\cos(k_y)$ (dotted line).

elg of the propagators which neglects strong renormalizations from interactions as well as impurities.

From this work we conclude that including the SF contribution in the Raman response solves the previously unexplained sensitivity of the $A_{1g}$ response to small changes in the Raman vertex. Also, within our model it is now possible to obtain the correct relative peak positions of the $A_{1g}$ and the $B_{1g}$ scattering geometries. Whereas the SF (two-magnon) contribution controls the $A_{1g}$ peak, the $B_{1g}$ and $B_{2g}$ scattering geometries are essentially unaffected and determined by pair breaking processes alone.

We would like to thank R. Hackl for numerous discussions. One of the authors (F.V.) would like to thank the Gottlieb Daimler and Karl Benz Foundation for financial support. This work was partially supported by the Deutsche Forschungsgemeinschaft through SFB 484.

[12] Note that the term “screening” has been used to describe the backflow yielding the second term in Eq. (3). However, the backflow is independent of the charge of the carriers and comes into play solely from the pair interactions responsible for superconductivity. It yields the well known Anderson-Bogoliubov mode which restores gauge invariance. Details can be found in Ref. [3].
