Abstract—Random linear network coding is a particularly decentralized approach to the multicast problem. Use of random network codes introduces a non-zero probability however that some sinks will not be able to successfully decode the required sources. One of the main theoretical motivations for random network codes stems from the lower bound on the probability of successful decoding reported by Ho et. al. (2003). This result demonstrates that all sinks in a linearly solvable network can successfully decode all sources provided that the random code field size is large enough. This paper develops a new bound on the probability of successful decoding.

I. INTRODUCTION

It has been recently proved that network layer coding can increase throughput, particularly for multicast scenarios [1]. It is also known that linear network codes [2] can achieve max-flow upper bounds on the throughput in a single source multicast network. The algebraic approach of [3] is particularly useful in the design and analysis of linear network codes, and we adopt the notation and terminology of that paper.

Random networks codes [4], [5] are linear network codes in which the encoding coefficients are chosen randomly from a finite field. The sink nodes can decode correctly if and only if the overall transfer matrix from the sources to each sink is invertible. One of the main theoretical results for random network codes consists of the following lower bound on the probability of successful decoding [4], assuming that the underlying network is linearly solvable over \( \mathbb{F}_q \) (i.e. there exists a linear code which satisfies the multicast requirements).

For a network code in which some of the code coefficients are chosen independently and uniformly from a finite field with cardinality \( q \), the probability that all \( d \) receivers can decode the source processes is at least

\[
\left( 1 - \frac{d}{q} \right)^\nu
\]

(1)

where \( \nu \) is the maximum number of links receiving signals with independent random coefficients in any set of links constituting a flow solution from all sources to any receiver [5].

A looser bound (subject to the same conditions as above) which depends only on \( \eta \), the total number of edges receiving signals with independent random coefficients is given by [4], [6]

\[
\left( 1 - \frac{d}{q} \right)^\eta
\]

(2)

Thus provided a linear solution over \( \mathbb{F}_q \) exists in the first place, the probability of successful decoding can be made as close to one as desired, by increasing the field size \( q \). The bounds (1) and (2) rely on the special structure of the determinant polynomial of the transfer matrix of the network.

This paper develops the following new lower bound.

**Theorem 1:** Consider a network code in which \( \eta \) edges receive signals with independent random coefficients chosen independently and uniformly from a finite field with cardinality \( q \). If there is some choice of coefficients for these \( \eta \) edges that results in a solution over \( \mathbb{F}_q \) then the probability that all receivers can decode the source processes is at least

\[
\left( 1 - \frac{1}{q} \right)^\eta
\]

(3)

Our approach for the proof of this theorem is to identify a critical sub-matrix of the Edmonds matrix whose non-singularity is a necessary and sufficient condition for decoding success. This critical matrix is different for each sink in the network. The new bound results directly from a nesting property of the critical matrices.

In the new bound, the field size \( q \) required to attain a given probability of success depends only on the number of edges with random coefficients, and not on the number of sinks. The resulting \( d \)-fold reduction in the required \( q \) could be significant. We emphasize that (3), like (1) applies only when the underlying network is solvable over \( \mathbb{F}_q \). This is a consequence of the conditions for applicability of the Schwartz-Zippel inequality, which is used in the proof of both bounds. Thus (3) does not imply the universal existence of binary solutions for every network. The bounds (1), (2) and (3) only provide lower bounds for a given \( q \) when the network is solvable over \( \mathbb{F}_q \).

We further conjecture that for large random networks satisfying certain properties, the success probability behaves as

\[
\prod_{i=1}^{E} \left( 1 - \frac{1}{q^i} \right)
\]

(4)

where \( E \) is the total number of links in the network.

The paper is organized as follows: Section II presents our model and introduces some algebraic notation. Section III develops the new bound (3), while Section IV discusses random graphs, leading to the conjecture (4).

II. NETWORK CODING MODEL

We adopt the model from [3]. The network is represented by a directed acyclic graph \( \mathcal{G} = (\mathcal{V}, \mathcal{E}) \) with \( \mathcal{V} = |\mathcal{V}| \) nodes and \( E = |\mathcal{E}| \) edges. There are \( r \) independent, discrete source
processes with messages belonging to $\mathbb{F}_q$, and $d \geq 1$ receivers. Each receiver node has $L \geq r$ incoming edges. The multicast requirement is that each receiver node can decode every source message from the signals on its incident edges.

Each edge $e \in \mathcal{E}$ is incident to node $v \in \mathcal{V}$ if $v = \text{head}(e)$, or is an outgoing edge if $v = \text{tail}(l)$. The in-degree of a node $v$ is $d_{\text{in}}(v)$ and the out-degree is $d_{\text{out}}(v)$. The time unit is chosen such that the capacity of each link is one bit per unit time and edges with larger capacity are modeled as parallel edges. Without loss of generality, it can be assumed that each source is associated with a source node $s_\alpha \in \mathcal{V}$ with $d_{\text{in}}(s_\alpha) = 0$ and $d_{\text{out}}(s_\alpha) = 1$, $\alpha = 1, 2, \ldots, r$. Similarly, each sink node $t_\beta$ has $d_{\text{in}}(t_\beta) = r$ and $d_{\text{out}}(t_\beta) = 0$, $\beta = 1, 2, \ldots, d$ (it is always possible to obtain such a graph by introducing auxiliary nodes and edges). It will further be assumed that edges are labeled ancestrally.

A scalar linear network code for $G$ is an assignment of linear encoding functions $f_v : \mathbb{F}_q^{d_{\text{in}}(v)} \mapsto \mathbb{F}_q^{d_{\text{out}}(v)}$ to each node $v \in \mathcal{V}$. Such codes are sufficient for the multicast problem on acyclic delay networks. Following [3], define the encoding matrix $F \in \mathbb{F}_q^{d \times E}$ where $F_{ij}$ is the coefficient applied to the symbol incoming on edge $i \in \mathcal{E}$ for contribution to outgoing edge $j \in \mathcal{E}$. According to the assumption of ancestral ordering, $F$ is strictly upper triangular. Similarly, the source matrix $A \in \mathbb{F}_q^{\alpha \times E}$ maps messages onto outgoing source edges and the sink matrix $B_\beta \in \mathbb{F}_q^{\beta \times E}$ maps incoming sink edges onto the sinks $t_\beta \in \mathcal{V}$, $\beta = 1, 2, \ldots, d$.

Let $x \in \mathbb{F}_q^{\alpha \times 1}$ be a row vector representing the source messages. Then the received vector of symbols $y_\beta \in \mathbb{F}_q^{\beta \times 1}$ at sink $\beta = 1, 2, \ldots, d$ is given by

$$y_\beta = xM_\beta$$

where

$$M_\beta = A(I - F)^{-1}B_\beta^T$$

Each sink can decode all sources if and only if $\det(A(I - F)^{-1}B_\beta^T) \neq 0$ for every $\beta = 1, 2, \ldots, d$, or equivalently if the Edmonds matrix

$$Z_\beta = \begin{bmatrix} A & 0 \\ I - F & B_\beta^T \end{bmatrix}$$

is non-singular.

Considering the entries of $A$, $F$ and $B_\beta$ as variables, the Leibniz determinant formula provides a way of writing $\det Z_\beta$ as a multivariate polynomial $P_\beta$ in the $a_{ij}, f_{ij}, b_{ij}$. Furthermore, this multivariate polynomial has degree at most $\nu$ but is linear in each variable individually. Therefore the product

$$P = \prod_\beta P_\beta$$

has degree $d\nu$, with each variable of degree $d$ or less.

The lower bound (1) results from a modified Schwartz-Zippel bound, which takes into account the individual variable degree constraint of $P_\beta$ [5, Lemma 1]. We reproduce this lemma for reference.

**Lemma 1:** Let $P$ be a multivariate polynomial of degree $d\nu$, with the exponent of any individual variable at most $d$. Let each variable be chosen uniformly from $\mathbb{F}_q$. Then if $P$ is not identically zero,

$$\Pr (P \neq 0) \geq \left(1 - \frac{d}{q}\right)^\nu. \tag{6}$$

We make two remarks on this approach. First, application of Lemma 1 to $P$ as defined in (5) implies an independence of the events $P_{\beta_1} = 0$ and $P_{\beta_2} = 0$. Depending on the structure of the network, these events may be strongly dependent. For example, consider $P_1 = P_2 = \cdots = P_d$, meaning all sinks have identical incoming signals ($B_1 = B_2 = \cdots = B_d$). Then Lemma 1 yields a lower bound $(1 - d/q)^\nu$, rather than $(1 - 1/q)^\nu$. Obviously this is an extreme example, yet it illustrates the point that (1) may be loose.

Secondly, the modified Schwartz-Zippel bound itself can be very loose, as the following example shows. Let $H \in \mathbb{F}_q^{m \times m}$ with each entry $h_{ij}$ chosen independently with a uniform distribution on $\mathbb{F}_q$. Then it is well known that

$$\Pr (\det H \neq 0) = \pi_{m,q}(q) = \prod_{i=1}^m \left(1 - q^{-i}\right). \tag{7}$$

In contrast, Lemma 1 gives the lower bound

$$\Pr (\det H \neq 0) \geq (1 - q^{-1})^m, \tag{8}$$

which also could be obtained from (7) by lower bounding each term in the product by the minimum term $(1 - q^{-1})$.

We emphasize that (6) applies only when $P$ is not identically zero for every choice of variables (e.g. all coefficients are zero). This precludes application of (6) to non-solvable networks, i.e. networks where every choice of $F$ makes $Z_\beta$ singular and hence $P = 0$.

In Section III we partially address the dependency between the $P_\beta$, while in Section V we consider large random networks, where we also discuss the extent to which (7) improves (6).

### III. THE NEW BOUND

According to our assumption regarding sources and sinks, and the ancestral ordering of edges, we can further assume without loss of generality that

$$A = \begin{bmatrix} I_r & 0 \\ 0 & 0 \end{bmatrix} \quad B_\beta = \begin{bmatrix} 0_{r \times k_\beta} & I_r & 0_{r \times (E - r - k_\beta)} \\ 0_{r \times k_\beta} & 0 \end{bmatrix}, \beta = 1, 2, \ldots, d$$

where $k_1 > r$ and $k_\beta > r + k_{\beta - 1}$, $\beta > 1$. This means that the sources inject messages into the network via edges 1, 2, ..., $r$ and that each sink observes signals on $r$ consecutively numbered edges. No sink shares edges with any other sink or source. See Figure 1 for an example of how to arrive at this formulation.

Then the Edmonds matrix for sink $\beta$ has the following structure:

$$Z_\beta = \begin{bmatrix} I_r & 0 & 0 & 0 \\ U_1 & W_{11} & W_{12} & W_{13} & 0 \\ 0 & U_2 & W_{21} & W_{22} & 0 \\ 0 & 0 & U_3 & W_{31} & I_r \\ 0 & 0 & 0 & U_4 & 0 \end{bmatrix} \tag{9}$$
where the $U_i$ are square, upper triangular with diagonal elements all equal to 1. The matrices $U_1$ and $U_3$ are $r \times r$, $U_2$ is $(k_β - 2r) \times (k_β - 2r)$ and $U_4$ is $(E - r \times k_β) \times (E - r \times k_β)$.

**Definition 1:** The critical matrix for sink $β$ is the following $(k_β - r) \times (k_β - r)$ principal sub-matrix of $Z_β$,

$$C_β = \begin{pmatrix} W_{11} & W_{12} \\ W_{21} & W_{22} \end{pmatrix}.$$  

**Lemma 2:** The determinant of the Edmonds matrix for sink $β$ has the same magnitude as the determinant of its critical matrix.

$$|\det Z_β| = |\det C_β|$$

**Proof:** Straightforward from either the Laplace expansion of $\det Z_β$, or repeated application of the partitioned matrix determinant formula.

We can immediately apply Lemma 2 to $\det C_β$ to bound the probability for a given sink

$$\Pr(\det Z_β \neq 0) \leq \Pr(\det C_β \neq 0) \geq \left(1 - \frac{1}{q}\right)^{η_β},$$

where $η_β$ is the number of columns in $C_β$ with variable terms, i.e. the number of edges in the subset $\{r + 1, r + 2, \ldots, k_β\}$ receiving signals with random coefficients.

For the $d$ receiver problem, we have the following very useful property of the critical matrices, which is guaranteed by their construction.

**Lemma 3 (Nesting of critical matrices):** $C_β_i$ is a principal sub-matrix of $C_β_β$ for $β_2 > β_1$.

Hence each critical matrix $C_β$ has as nested principal sub-matrices, all the critical matrices for sinks $1, 2, \ldots, β - 1$.

**Proof:** [Proof of main result 3] Let $E_β, β = 1, 2, \ldots, d$ be the event that sink $β$ can decode. By Lemma 2 $E_β$ $\iff$ $\det Z_β \neq 0$ $\iff$ $\det C_β \neq 0$. Now the probability that all sinks can decode is given by

$$\Pr\left(\bigcap_{β=1}^{d} E_β\right) = \Pr(E_1 \Pr(E_2 \mid E_1) \ldots \Pr(E_β \mid E_1 \ldots E_{β-1})$$

(12)

Now consider $\Pr(E_m \mid E_1, \ldots, E_{m-1}) = \Pr(\det C_m \neq 0 \mid det C_1 \neq 0, \ldots, det C_{m-1} \neq 0)$ for some $2 \leq m \leq β$. By Lemma 3 $C_m$ can be partitioned

$$C_m = \begin{pmatrix} C_{m-1} & U \\ V & W \end{pmatrix}$$

for appropriate choices of $U, V, W$.

Conditioned on $\det C_{m-1} \neq 0$, we can use the partitioned matrix determinant formula to write

$$\det C_m = \det(C_{m-1})\det(W - VC_{m-1}^{-1}U),$$

(13)

which (conditioned on $\det C_{m-1} \neq 0$) is zero if and only if $\det(W - VC_{m-1}^{-1}U) = 0$.

Let $ϕ_m$ be the multivariate polynomial corresponding to $\det C_m$, and let $σ_{m-1}$ be the multivariate polynomial corresponding to $\det(W - VC_{m-1}^{-1}U)$. Then from (13) $\deg ϕ_m = \deg φ_{m-1} + \deg σ_{m-1}$. This relation also holds for the degree of any individual variable. From the Leibniz formula and the structure of the Edmonds matrix (as explained previously for $P_β$), we also know that the individual degree of any variable in $ϕ_m$ or $φ_{m-1}$ is zero or one. Hence

$$\deg σ_{m-1} = \deg φ_{m} - \deg φ_{m-1},$$

and the degree of any individual variable in $σ_{m-1}$ is at most 1. Collecting results so far and applying Lemma 1

$$\Pr(E_m \mid E_1, \ldots, E_{m-1}) = \Pr(\det(W - VC_{m-1}^{-1}U) \neq 0)$$

$$= \Pr(\langle σ_{m-1} \neq 0 \rangle)$$

$$\leq \left(1 - \frac{1}{q}\right)^{\deg φ_{m} - \deg φ_{m-1}}$$

Finally, substitution into (12) results in a telescoping sum for the exponents, $\deg φ_1 + \deg φ_2 - \deg φ_1 + \deg φ_2 - \deg φ_2 + \ldots$, leaving only

$$\Pr\left(\bigcap_{β=1}^{d} E_β\right) \geq \left(1 - \frac{1}{q}\right)^{\deg φ_{d}}$$

This directly yields 3 via $\nu \leq \deg φ_{d} = ν d \leq E$. Let

$$z(d, q) = \frac{\log(1 - d/q)}{\log(1 - 1/q)}.$$ 

Then (3) is tighter than (1) whenever

$$\eta < ν z(d, q).$$

Furthermore, $z(d, q) > d$ and

$$\lim_{q \to d} z(d, q) = \infty$$

$$\lim_{q \to \infty} z(d, q) = d.$$ 

Roughly speaking, the new bound is tighter for networks with $E = O(ν d)$ and sufficiently small $q$.

In some instances it may be useful to have a bound which depends only on the total number of edges carrying signals with random coefficients. Replacing $ν$ with $η$ in (1) results in (2) which is looser than (3), since

$$(1 - d/q)^{η} < (1 - 1/q)^{η}.$$ 

Note that successful decoding at a particular sink $β$ in general depends on only part of $C_β$. There can be a much smaller sub-matrix that determines singularity, for example, $C_β$ might be block diagonal, with successful decoding of sink $β$ depending only on one of the blocks (this case arises when there are disjoint paths from the sources to each sink). Thus $C_β$ may be larger than strictly required for analysis of sink $β$ alone, however defining the critical matrix this way yields the nesting property that results in the new bound.
IV. EXAMPLE: THE BUTTERFLY NETWORK
Figure 1 shows the well-known butterfly network, with additional nodes and edges introduced in order to satisfy our assumptions on sources and sinks. The source $s$ has $r = 2$ messages, and the edge labels indicate the edge ordering. Edges 1 and 2 carry the two messages from the source, while edges 12 resp. 13 duplicate the signals on edges 5 resp. 10, and edges 14 resp. 15 duplicate 8 resp. 11. Supposing that all other edges carry random linear combinations of signals, $\nu = 7$ and $\eta = 9$.

Figure 2 shows the structure of the Edmonds matrix $Z_1$, and the nested critical matrices $C_1$ and $C_2$. To see how the nesting arises, $B_2$ has been placed alongside. For clarity, most of the zeros have been omitted from each matrix. The solid disks represent random entries of $F$.

V. RANDOM GRAPHS
Successful decoding for a particular sink $\beta$ depends on the non-singularity of its critical matrix $C_\beta$. To obtain (3) we used Lemma 1 to bound the probability that this matrix is non-singular. It is interesting to consider however circumstances under which (7) might be applicable, providing an even tighter bound.

There are two main obstacles to the application of (7) for determination of the probability that $\det C_\beta \neq 0$. Firstly, (7) applies to “full” matrices, with each element chosen independently and uniformly from $\mathbb{F}_q$. In contrast, $C_\beta$ is of the form (10), with all elements below the $r$-th diagonal equal to zero (the strictly lower triangular part of $U_2$). Secondly, the non-zero elements in the upper portion (upper triangular part of $U_2$ and all of $W_{11}$, $W_{12}$ and $W_{21}$) of $C_\beta$ are determined by the topology of the network itself. For a sparsely connected network, the proportion of zeros in this part of the matrix will greatly exceed $1/q$.

Assuming that the random network code coefficients are chosen from the non-zero elements of $\mathbb{F}_q$, the total number of non-zero elements in $F$ is

$$\sigma = \sum_{v \in V} d_{\text{in}}(v) d_{\text{out}}(v) \leq E^2.$$ 

Let $\rho = \sigma / E^2$ be the proportion of non-zero elements. Ignoring the structure required by (10), generate a random $m \times m$ matrix $C^{(m)}$ with elements identically distributed according to

$$\Pr (c_{ij} = f) = \begin{cases} 1 - \rho & f = 0 \\ \frac{\rho}{\eta - 1} & f \neq 0 \end{cases}$$
It is a remarkable fact that provided \( \rho \) does not tend to zero or one too quickly with \( m \),

\[
\lim_{m \to \infty} \Pr \left( \det C^{(m)} \neq 0 \right) = \pi_m(q).
\]

See [7] for a discussion of this threshold effect. Conditioned on the event that \( C^{(m)} \) has no all-zero rows or columns (if it did, the network flow would anyway be infeasible regardless of choice of code), the requirement is

\[
\rho > \frac{1}{m} \left( \frac{1}{2} \log m + \log \log m \right).
\]

This result even holds for independent, but non-identically distributed entries, as discussed by Cooper [7].

Now for sufficiently small \( \rho \), \( C^{(m)} \) can be permuted into the form (10). This leads us to conjecture that there exist conditions on \( \sigma \) such that \( \pi_m(q) \) is the success probability for a large, randomly generated network with a given degree distribution. The remainder of this section analyzes some properties of \( \pi_m(q) \), and demonstrates the improvement that may be obtained compared to (8).

To guarantee a particular probability \( p \) using (8), the field size \( q \) must satisfy

\[
q \geq \frac{1}{1 - p^{1/m}} = \frac{1}{2} + m \log \frac{1}{p} + O \left( \frac{1}{m} \right).
\]

Hence the required field size increases linearly with the size of the matrix.

Let \( \pi_\infty(q) = \lim_{m \to \infty} \pi_m(q) \) then

\[
\pi_\infty(q) = \prod_{i=1}^{\infty} (1 - q^{-i}) = q^{1/24} \left( \frac{1}{2} \vartheta_1' \left( q^{-1/2} \right) \right)^{1/3},
\]

where \( \vartheta_1 \) is the Jacobi theta function [8, Equation 8.181.3] and

\[
\vartheta_1'(q) = \frac{\partial}{\partial z} \vartheta_1(z, q) \bigg|_{z=0} = 2 \sum_{i=0}^{\infty} (-1)^i (1 + 2i) q^{-\frac{1}{2}(i + \frac{1}{2})^2}.
\]

Truncating the latter series gives the following lower bound,

\[
\pi_\infty(q) \geq \left( 1 - \frac{3}{x} \right)^{1/3}.
\]

This lower bound is compared to \( \pi_\infty \) for the first 20 primes in Figure [4]. For a given probability \( p \) in [7], the required field size \( q \) for \( m \to \infty \) satisfies

\[
q \geq \frac{3}{1 - p^3}.
\]

which does not depend on \( m \).

VI. CONCLUDING REMARKS

Random network coding is a promising decentralized approach for multicast. One of the main implementation considerations is the size of the finite field required to achieve a specified probability that every sink can decode every source. This paper presented a new bound on the success probability, which in certain circumstances is tighter than the previous bound. We also presented a heuristic argument that motivates the investigation of tighter bounds for large random networks, based on the distribution of rank of large random finite field matrices.
