**Abstract**

Single-stranded DNA-binding proteins (SSB) are ubiquitous proteins found in all DNA-dependent cellular processes. Typical SSB proteins have an N-terminal Oligonucleotide-Binding (OB) fold, a Proline/Glycine rich region, followed by a C-terminal acidic tail. In the genome of the heterocystous nitrogen-fixing cyanobacterium, *Anabaena* sp. strain PCC7120, *alr0088* and *alr7579* are annotated as coding for SSB, but are truncated and have only the OB-fold. *In silico* analysis of whole genome of *Anabaena* sp. strain PCC7120 revealed the presence of another ORF ‘all4779’, annotated as a hypothetical protein, but having an N-terminal OB-fold, a P/G-rich region and a C-terminal acidic tail. Biochemical characterisation of all three purified recombinant proteins revealed that they exist either as monomer or dimer and bind ssDNA, but differently. The *All4779* bound ssDNA in two binding modes i.e. (All4779)$_{35}$ and (All4779)$_{66}$ depending on salt concentration and with a binding affinity similar to that of *Escherichia coli* SSB. On the other hand, *Alr0088* bound in a single binding mode of 50-mer and *Alr7579* only to large stretches of ssDNA, suggesting that *All4779*, in all likelihood, is the major typical bacterial SSB in *Anabaena*. Overexpression of *All4779* in *Anabaena* sp. strain PCC7120 led to enhancement of tolerance to DNA-damaging stresses, such as γ-rays, UV-irradiation, desiccation and mitomycinC exposure. The tolerance appears to be a consequence of reduced DNA damage or efficient DNA repair due to increased availability of *All4779*. The ORF *all4779* is proposed to be re-annotated as *Anabaena* ssb gene.

**Introduction**

Single-stranded DNA-binding proteins (SSB) are ubiquitous proteins found in all bacteria. The SSB proteins are characterised by their non-specific binding to single-stranded DNA (ssDNA) and active participation in the maintenance of genome integrity (DNA repair) as well as genetic information transfer (replication and transcription) [1]. A typical SSB monomer consists of (a) an N-terminal region having several conserved residues responsible for binding to ssDNA, tetramerisation and stabilization of monomer fold [2], and (b) a C-terminal region which displays a low sequence conservation except for the last few amino acids (known as acidic tail), and is responsible for protein-protein interactions and recruitment of DNA interactive proteins [3]. The highly conserved OB-fold has been extensively described for *Escherichia coli* SSB protein [1]. Deletion of C-terminus diminishes recruitment of other DNA interacting proteins [3], but enhances the affinity of N-terminus to ssDNA [4]. The spacer region between the N-terminal OB-fold and C-terminal acidic tail is rich in proline/glycine (P/G) residues and is thought to modulate the strength of DNA binding, possibly by distancing the highly negatively charged C-terminal end from the positively charged DNA binding N-terminal domain [5].

Nitrogen-fixing cyanobacteria, such as strains of *Anabaena* and *Nostoc* exhibit tolerance to a variety of abiotic stresses such as salinity, desiccation, heat and radiation [6,7], strongly indicative of a robust mechanism of DNA repair in these microbes [8]. Unfortunately, genes/proteins involved in DNA metabolism of cyanobacteria have not received adequate attention. The SSB protein is a key protein involved in all DNA related cellular activities. In the genomic database of *Anabaena* sp. strain PCC7120 (hereafter referred to as *Anabaena* 7120), two ORFs ‘*alr0088*’ and ‘*alr7579*’ are annotated as coding for SSB-like proteins (http://genome.microbedb.jp/cyanobase/Anabaena) and exhibit 28–30% homology at amino acid level with EcoSSB, and about 42% homologous to each other. However, BLAST search [9] of the amino acid sequence of these two proteins show that the protein sequence is terminated immediately after the N-terminal OB-fold region and have no region corresponding to either the P/G spacer or the C-terminal acidic tail. Since, C-terminal acidic tail is essential for interaction with other DNA replication/repair/recombination proteins [3], it seems unlikely that the proteins encoded by these two ORFs can perform all the functions of SSB proteins. However, this does not rule out that they are genuine SSBs, since the second SSB (SsbB) of naturally transformable bacteria, such as *Bacillus subtilis*, lacks the C-terminal acidic tail,
but functions as a SSB and is involved in genetic recombination [10,11]. Alr0088 and Alr7579 exhibit about 36-38% overall homology with BsSsbB. An in silico search for a SSB-like protein with the C-terminal region (i.e. the spacer region and acidic tail) in the genome of *Anabaena* 7120, revealed the ORF 'all4779'. The ORF encodes a 182 amino acid long protein with an N-terminal OB-fold, a P/G rich spacer region and a C-terminal acidic tail but has been annotated as a hypothetical protein possibly due to its lower homology (15–18%) with other bacterial SSBs. The homologs of the two truncated SSB-like proteins as well as hypothetical SSB-like protein of *Anabaena* 7120 are found across all cyanobacterial genomes (http://genome.microbedb.jp/cyanobase).

In the present work, we cloned, overexpressed, purified and biochemically characterised Alr0088, Alr7579 and All4779 proteins. All three proteins existed in monomeric and dimeric biochemically characterised Alr0088, Alr7579 and All4779 cyanobacterial genomes (http://genome.microbedb.jp/cyanobase).

### Materials and Methods

#### Organism and Growth Conditions

*E. coli* cells were grown in Luria–Bertani (LB) medium at 37°C with shaking (150 rpm). When required antibiotics [34 μg chloramphenicol mL⁻¹ (Cm₃₄), 50 μg kanamycin mL⁻¹ (Kan₅₀), or 100 μg carbenicillin mL⁻¹ (Cb₁₀₀)] were used in culture media. Axenic cultures of *Anabaena* 7120 were grown in BG-11 liquid medium, pH 7.0 [12] in the absence of combined nitrogen (BG-11, N⁻) under stationary conditions with continuous illumination (30 μE m⁻² s⁻¹) at 27°C±2°C. Recombinant *Anabaena* strains were grown in the presence of 10 μg neomycin mL⁻¹ (Nm₁₀) in BG-11 liquid media or with 25 μg neomycin mL⁻¹ (Nm₂₅) on BG-11 agar plates. Growth was assessed in terms of chlorophyll *a* content per ml of culture as described earlier [13]. Cell survival was assessed in terms of colony forming units (cfu) by plating 100 μl of the culture on to BG-11, N⁻ agar plates followed by incubation under illumination for 10 days as described earlier [14].

Three-day-old nitrogen-fixing *Anabaena* cultures were concentrated to a chlorophyll *a* density of 10 μg mL⁻¹, prior to subjecting them to one of the following stresses: (i) 6 kGy of ¹⁶⁰ Co γ-rays at a dose rate of 4.5 kGy h⁻¹, or (ii) 6 days of desiccation or in humid chamber (control), or (iii) 0–4 μg mitomycinC (mitC) mL⁻¹ for 30 min, or (iv) exposure to 0–1.5 kJ UV-B (280 nm) (dose rate 5 J m⁻² sec⁻¹) for different duration. Survival in response to stress, and post-stress recovery were compared with unstressed/control cultures grown under illumination at 27°C±2°C as described earlier [14].

#### Generation of Plasmid Constructs for Overexpression of Proteins in *E. coli*

Different amplicons (alr0088, alr7579, all4779) were generated by PCR amplification of *Anabaena* 7120 genomic DNA (100 ng) using gene specific primers (as indicated in Table 1), 1 μM dNTPs and 1U Taq DNA polymerase in Taq buffer (Bangalore Genei, India). These amplicons were individually digested with Ndel and BamHI restriction endonucleases and ligated to the expression

### Table 1. Primers used and PCR amplicons generated in this study.

| Primers       | Nucleotide Sequence* | R.E.   | Amplicon** |
|---------------|----------------------|--------|------------|
| alr0088 Fwd  | 5’ GCCCATATGACATTTCAACGGTGC 3’ | Ndel   | alr0088 ORF (0.35 kb) |

Figure 1. Bioinformatic analysis of Alr0088, Alr7579 and All4779 proteins of Anabaena 7120. (A) Conserved Domain Database (CDD) analysis of Anabaena Alr0088, Alr7579 and All4779 proteins and E. coli SSB (EcoSSB) protein. The OB-fold corresponding ssDNA binding region, dimer and tetramer interfaces for all the proteins are indicated. (B) Comparison of homology between predicted amino acid sequence of All4779 and EcoSSB. The identical amino acids are indicated by letters and similar amino acids with a ‘+’ sign. The proline (P) and glycine (G) residues beyond the OB fold are shown in larger font, while the acidic residues at the C-terminal end are in bold and underlined. The numbers on the left and right hand side correspond to amino acid residues.

doi:10.1371/journal.pone.0093592.g001
vector pET16b (Table 2), having His_10-tag at the 5' end, at identical restriction sites. The resulting plasmid constructs were designated as pETalr0088, pETalr7579 and pETall4779 respectively (Table 2). DNA insert of all three plasmids were sequenced on both strands using Sanger’s dideoxy method and were found to be completely identical to the corresponding nucleotide sequences available in the genomic database. The nucleotide sequences corresponding to alr0088, alr7579 and all4779 respectively were submitted to GenBank (GenBank Accession Nos. GU225949, GU225950, GU225951).

Overexpression and Purification of His-tagged Proteins
The plasmids pETalr0088, pETalr7579 and pETall4779 (Table 2) were transformed into E. coli BL21(pLysS) and transformants selected on LBCm34Cb100 plates (Table 3). Proteins were overexpressed from the respective logarithmic phase cultures of E. coli upon addition of 1 mM IPTG for 3 h at 37°C. The recombinant His-tagged proteins (Alr0088, Alr7579 and All4779) were extracted in lysis buffer (20 mM Tris-HCl, pH 8, 0.5 M NaCl, 5 mM imidazole and 0.1% TritonX-100) by sonication and purified by Ni-NTA affinity chromatography (Qiagen, Germany) using different concentrations of imidazole ranging from 10–1000 mM as described earlier. The proteins were eluted individually in 1 M imidazole fraction and visualised by electrophoretic separation on 14% SDS-polyacrylamide gel followed by staining with Coomassie Brilliant Blue (CBB) G-250. The purified proteins were individually cross-linked using glutaraldehyde, as described earlier [15], followed by precipitation of protein with cold acetone. The pellet was air dried, solubilised in 1X Laemmli’s buffer by heating at 80°C for 10 min, separated by SDS-PAGE and visualized by staining with CBB G-250.

Molecular mass determination of native purified proteins was carried out by gel filtration chromatography using Superdex HR200 column. The column was equilibrated with Tris-NaCl buffer and standard graph obtained using the following proteins: Myosin (200 kDa), β-galactosidase (116 kDa), Phosphorylase-b (97.4 kDa), Bovine Serum Albumin (66 kDa), Chicken Albumin (45 kDa), Carbonic Anhydrase (29 kDa) and RNase A (13.7 kDa) was drawn to calculate the molecular mass of the eluted native Anabaena proteins depending on their elution volume. The position of the eluted proteins has been depicted by ‘star’ and ‘triangle’ symbols. The vertical and horizontal lines from the two symbols indicate the elution volume and the corresponding log of molecular mass.

doi:10.1371/journal.pone.0093592.g002

The purified recombinant native proteins were individually cross-linked using glutaraldehyde, as described earlier [15], followed by precipitation of protein with cold acetone. The pellet was air dried, solubilised in 1X Laemmli’s buffer by heating at 80°C for 10 min, separated by SDS-PAGE and visualized by staining with CBB G-250.

Molecular mass determination of native purified proteins was carried out by gel filtration chromatography using Superdex HR200 column. The column was equilibrated with Tris-NaCl buffer and standard graph obtained using the following proteins: Myosin (200 kDa), β-galactosidase (116 kDa), Phosphorylase-b (97.4 kDa), Bovine Serum Albumin (66 kDa), Chicken Albumin (45 kDa), Carbonic Anhydrase (29 kDa) and RNase A (13.7 kDa). Molecular mass of the three Anabaena proteins was calculated from the standard graph on the basis of the elution volume. Presence of protein in different elutes/fractions was detected by measuring absorbance at 280 nm.

Electrophoretic Mobility Shift Assay (EMSA)
A 75-mer oligonucleotide (10 ng) was end-labelled with γ-32P-ATP using Polynucleotide Kinase. The labelled oligo was incubated in the presence of specified concentrations of the Alr0088, Alr7579 and All4779 proteins in binding buffer [20 mM Tris-HCl, pH 8, 1 mM MgCl2, 100 mM KCl, 8 mM Dithiothreitol (DTT), 4% sucrose, 80 µg mL⁻¹ Bovine Serum Albumin (BSA)] for 30 min at room temperature and electrophoretically separated subsequently on 6% non-denaturing polyacrylamide gel at 150 V for 2 h in 1X Tris-borate EDTA (TBE) buffer. Imaging of the radioactive gel was carried out using Phosphorimagerno Typhoon Trio Variable mode imager (Wipro-GE-HealthCare, USA).
Fluorescence Measurements

All three proteins showed maximum excitation at 282 nm. The emission maxima were found to be 310, 340 and 335 nm respectively for Alr0088, Alr7579 and All4779 proteins in 20 mM Tris-HCl, pH 8, 1 mM EDTA buffer. The change in the intensity of the emitted fluorescence was measured in the presence of increasing concentration of ssDNA [poly(dT) or M13 ssDNA]. The graph of relative fluorescence (%) as a function of poly(dT) concentration was used to determine the binding constant for the individual proteins to ssDNA as described earlier [16]. The binding constants were calculated as the reciprocal of the concentration of poly(dT) at which 50% fluorescence compared to the initial 100% was detected. The graph depicting quenching expressed as the ratio of difference in fluorescence to initial fluorescence (ΔF/F0) as a function of the ratio of concentrations of poly(dT) and protein was used to determine the binding modes or occlusion site of the proteins as described earlier [17]. It corresponded to the [nt]poly(dT)/[Protein] value at the point of saturation of quenching of fluorescence. During titration, solutions were added from concentrated samples and correction for dilution was made as required. All fluorescence measurements were performed with Jasco spectrofluorimeter FP6500 (Japan) using a quartz cuvette of 1 cm path length at room temperature.

Western Blotting and Immuno-detection

The purified All4779 protein was used to raise specific polyclonal antibody (anti-All4779 antibody) in rabbit. Proteins were extracted from three-day-old wild type and recombinant Anabaena cultures in Laemmli’s buffer, separated by 14% SDS-PAGE followed by electroblotting on to nitrocellulose membrane. Immunodetection was carried out using the 1:5000 dilution of anti-All4779 antibody, followed by secondary anti-rabbit IgG antibody, coupled to alkaline phosphatase and colour development using NBT-BCIP.

Generation of Recombinant Anabaena Strains

The 0.55 kb NdeI-BamHI fragment from pETall4779 was ligated to pFPN vector (Table 2) [18] at the same restriction sites, resulting in the plasmid construct, pFPNall4779. The 0.81 kb SfiI-Apal fragment from pFPNall4779 was ligated to pAM1956 vector (Table 2) [19] digested with the identical restriction enzymes. The
resulting construct was designated as pAMall4779 (Table 2). In this construct, the gpmut2 gene (coding for Green Fluorescent Protein, GFP) is co-transcribed with the upstream all4779 gene from the PpsbA1 promoter, but the two transcripts are translated independently as described earlier [20]. Recombinant Anabaena strain overexpressing All4779 protein (Anall4779+) (Table 3) was generated by introducing the plasmid pAMall4779 into Anabaena by conjugation as described earlier [20], and repeated selection on BG-11 agar plates containing 17 mM NaNO3 (BG-11, N+) and Neo25, till completely segregated cells, uniformly expressing GFP, were obtained.

Results and Discussion

Bio-informatic Analysis of Alr0088, Alr7579 and All4779 Proteins

The alr0088, alr7579 and all4779 genes respectively encode 119, 127 and 182 amino acid long polypeptides (Figure 1A) with an estimated molecular mass of 13, 14 and 20 kDa. The prokaryotic SSBs are generally about 160–180 amino acids long, having a molecular mass of 17–18 kDa, except for SsbB of naturally transformable bacteria, which in case of BsSsbB is 113 amino acids long [11]. The SsbA protein of B. subtilis is 172 amino acids long, similar in size to EcoSSB [10]. Among the naturally non-transformable bacteria, the smallest known bacterial SSB are from the thermophilic bacteria, Thermotoga maritima (TmaSSB) and T. neapolitana (TneSSB) consisting of 141 and 142 amino acids respectively, having a single OB-fold domain and a C-terminal domain with the conserved DEPPF terminal amino acids [21].
Among eukaryotes, the HsmtSSB is 133 amino acids long and does not have the region corresponding to 1/3rd of the C-terminal region of EcoSSB [22]. Amino acid sequence analysis using Conserved Domain Database (CDD) [9] revealed the presence of a putative ssDNA-binding OB-fold domain and dimer/tetramer interface within N-terminal half in all three proteins similar to that in *E. coli* SSB (Figure 1A). All4779 additionally had a long C-terminal region similar to that observed for EcoSSB which comprised of a proline-rich region (19 residues) with two glycine residues, as compared to EcoSSB which is glycine rich (21 residues) and has 8 prolines in the corresponding region (Figure 1B). While multiple glycine residues allow flexibility in structure, multiple proline residues provide rigidity and kinks in the structure and thus no ordered structure results in gly-rich or pro-rich regions [23]. The proline-rich region of All4779 would also separate the positively charged N-terminal and the negatively charged C-terminal regions, similar to that in EcoSSB [5]. The N-terminal region of All4779 exhibited 26% identical and 48% similar amino acid residues and a nearly identical acidic tail compared to EcoSSB (Figure 1B). In spite of having an N-terminal OB-fold, P/G rich region and a C-terminal acidic tail, the low homology of All4779 to other known bacterial SSB proteins may possibly account for it not being annotated earlier as SSB-like protein in the genome database of *Anabaena* 7120, unlike Alr0088 and Alr7579 which show a greater homology than All4779 in the OB-fold region.

Biochemical Characterisation of *Anabaena* Alr0088, Alr7579 and All4779 Proteins

The *Anabaena* Alr0088, Alr7579 and All4779 proteins overexpressed in *E. coli* BL21(pLysS) cells were purified to near homogeneity using Ni-NTA affinity chromatography (Figure 2A).
Presence of dimer and tetramer interfaces in the amino acid sequence (Figure 1A) suggested possibility of formation of multimers by the protein. Alr0088 and Alr7579 were eluted in two distinct fractions and All4779 in a single fraction (Figure 2B) upon separation by gel filtration chromatography using Superdex HR200. On the basis of elution profile of standard proteins on the same matrix, the molecular mass of the different fractions was predicted as 14.1 kDa and 25.7 kDa for Alr0088, 14.5 kDa and 26.3 kDa for Alr7579 and 20.2 kDa for All4779 (Figure 2B). This indicated dimerisation of Alr0088 and Alr7579 proteins as against only the monomeric form detected for All4779 protein. Higher molecular forms of these proteins were not detected even at higher protein concentrations (data not shown). This did not conform to the bioinformatic prediction for the three proteins which indicate the presence of dimeric and tetrameric interfaces (Figure 1A). Further probing of multimeric status was carried out by cross-linking the native proteins with glutaraldehyde followed by separation by SDS-PAGE. Upon cross-linking, the dimeric forms corresponding to 32 kDa for Alr0088 (Figure 3A), 34 kDa for Alr7579 (Figure 3B) and 41 kDa for All4779 (Figure 3C) were detected, with the levels of the dimeric form being lowest for All4779. This could be the reason for the inability to detect a higher molecular weight peak during gel-filtration chromatography for All4779 (Figure 2B). In the presence of M13 ssDNA the levels of the dimeric 41 kDa form as well as a probable tetrameric form of ~82 kDa increased (Figure 3C). This suggested that All4779 attains the native multimeric conformation preferably in the presence of ssDNA. In case of Alr0088 and Alr7579, no effect...
on the levels of the dimeric form or generation of tetrameric form was observed even with ssDNA (data not shown). In general, bacterial SSB proteins function as tetramers [1], with the exception of thermophilic group of organisms (Thermus spp.) and the radioresistant microbe Deinococcus radiodurans [24] which function as dimer. However, the protomers of SSB of these organisms are twice the size of E. coli SSB and contain two OB-folds per monomer [24].

The DNA binding ability of the SSB-like proteins was assessed by Electrophoretic Mobility Shift Assay (EMSA) and fluorescence quenching techniques. Multiple shifts in the mobility of the 75-mer ss oligonucleotide was observed in the presence of Alr0088 (Fig. 3D). Increase in concentration beyond 0.2 µg Alr0088 did not result in any further shifts in mobility (data not shown). Alr7579 decreased the mobility of the 75-mer oligo only when used at very high concentrations of 1.2–1.4 µg (Fig. 3D). Presence of Alr7579 also resulted in detection of multiple bands differing in their mobility, but majority of the complex formed, even when low concentrations of 0.12 µg of All4779 was used, was detected near the well (Fig. 3D). Based on this, the binding efficiency for ssDNA seems to be maximum for All4779, followed by Alr0088 and the least for Alr7579. The binding affinity for each of these proteins for ssDNA was calculated by fluorescence quenching technique using poly(dT) as the ssDNA substrate.

The relative fluorescence of native Anabaena proteins Alr0088, Alr7579 and All4779, was measured as a function of increasing

**Figure 7.** Effect of All4779 overexpression on the survival and tolerance of Anabaena to DNA-damage inducing stresses. (A and B) Three day-old cultures were concentrated to 10 µg chl density mL⁻¹ and exposed to 6 kGy of ⁶⁷Co γ-irradiation or to 6 days of desiccation. (A) Survival was measured in terms of colony forming units immediately after irradiation (I) or desiccation (D) and compared with the respective unirradiated control (CI) or undesiccated control (CD). (B) The stressed and control cultures were washed, innoculated in fresh BG-11, N₂, Neo₂5 and allowed to recover under normal growth conditions for 7 days. Growth during post-irradiation/desiccation recovery was measured in terms of chlorophyll a content and expressed as percent of respective unirradiated/undesiccated controls. (C and D) Three-day-old cultures of recombinant strains AnpAM and All4779⁺ were concentrated to 10 µg chl mL⁻¹ density. (C) An 100 µl aliquot was spread on the corresponding BG-11, N₂, Neo₂5 agar plates and exposed to UV-B (0–1.5 kJ) (D) Culture aliquots were exposed to mitomycinC (0–4 µg ml⁻¹) for 30 min in liquid media followed by plating 100 µl on BG-11, N₂ Neo₂5 agar plate. Colonies were counted after 10 days of incubation at 27±2°C with constant illumination.

doi:10.1371/journal.pone.0093592.g007
concentration of poly(dT) at 20 mM NaCl. The relative fluorescence of (i) Alr0088 decreased to a maximum of 40% with ~450 nM poly(dT) (Figure 4A), (ii) Alr7579 showed less than 20% decrease (Figure 4B), and (iii) All4779 up to 40% of the initial fluorescence, but at much lower concentrations (~35 nM) of poly(dT) (Figure 4C). Based on this, the binding constant, as an average of three independent experiments, was calculated as 2.56 ± 0.4 x 10^6 M^-1 for Alr0088, 5.13 ± 0.71 x 10^6 M^-1 for All4779 and 6.76 x 10^6 M^-1 for EcoSSB (Figure 4C), which was comparable to that reported for EcoSSB (5.5 ± 1.5 x 10^6 M^-1) [4].

In the absence of C-terminal acidic tail, the binding affinity for ssDNA has been shown to increase 10-fold in case of EcoSSB [4,27]. Since, (SSB)65 mode of binding requires the tetramer, while in (SSB)65 mode, binding, at low and high salt concentrations respectively, shown (Table 2, Figure 6A) in the recombinant Anabaena strain, Anall4779 (Table 3). Due to growth under continuous illumination, the expression of the All4779 protein from the light-inducible pP/f promoter was expected to be constitutive. Co-overexpression of the Green Fluorescent Protein (GFP), coded by gfpmut2 in the pMAAll4779 plasmid, provided a handy tool to distinguish the fully segregated recombinant Anall4779 strain exhibiting green fluorescence, from the wild type Anabaena 7120 which exhibited red fluorescence upon excitation with λ_710 light (Figure 6B). It also ensured expression of the upstream gene. The overexpression of All4779 in Anall4779 cells was indeed confirmed by immunodetection with anti-All4779 antibody (Figure 6C). Under normal growth conditions, the nitrogen-fixing cultures of Anall4779 grew marginally slower than the wild type Anabaena 7120 cultures, and at rates comparable to the recombinant Anabaena strain harbouring pMA1956 vector, AnpAM (Table 3) [30] (Figure 5D). This is possibly due to the presence of neomycin in the growth medium used for recombinant strain.

The effect of overexpression of All4779 on the ability of Anabaena 7120 to tolerate DNA damage inducing stresses was analysed in response to two distinct types of DNA damages i.e. (i) γ-irradiation and desiccation which cause single strand and double strand breaks, and (ii) UV-B and mitomycinC which cause formation of pyrimidine dimers and DNA adducts respectively. The empty vector control recombinant strain, AnpAM exhibited about 55% and 44% survival upon exposure to 6 kGy of 60Co γ-rays or 6 days of desiccation respectively (Figure 7A). Upon constitutive overexpression of All4779 in Anall4779 cells, the survival increased to about 60% after exposure to 6 kGy of γ-rays and 70% after 6 days of desiccation (Figure 7A). The recovery of irradiated cultures of Anabaena, measured in terms of chlorophyll a content increased from about 50% to over 100% in cells overexpressing All4779 (Figure 7B) suggesting better tolerance to radiation. Such correlation was however, not found in post desiccation recovery, (Figure 7B), possibly due to additional stresses, such as osmotic stress experienced during desiccation followed by rehydration of these cells. Of the other two SSB-like proteins of Anabaena, overexpression of Alr0088 decreased the radiation tolerance of Anabaena, while that of Alr7579 had no effect [14]. This suggested that All4779 is the typical bacterial SSB of Anabaena, involved in the repair of single and double strand breaks in DNA, possibly as part of a larger DNA repair complex, which is yet to be identified.

Overexpression of All4779 was also beneficial in protection against stresses which caused formation of DNA adducts. The survival of AnpAM was about 75% and 11.8% respectively upon exposure to 0.75 and 1.5 kJ m^-2 of UV-B irradiation, which increased to 77% and 50% respectively in Anall4779 cells, overexpressing All4779 protein (Figure 7C). The beneficial effect of the constitutive overexpression of All4779 was more pro-

Physiological Role of All4779 Protein in Anabaena 7120

The All4779 protein was overexpressed in trans from the plasmid pMAAll4779 (Table 2, Figure 6A) in the recombinant Anabaena strain, Anall4779 (Table 3). The All4779 protein was overexpressed in trans from the plasmid pMAAll4779 (Table 2, Figure 6A) in the recombinant Anabaena strain, Anall4779 (Table 3). The All4779 protein was overexpressed in trans from the plasmid pMAAll4779 (Table 2, Figure 6A) in the recombinant Anabaena strain, Anall4779 (Table 3). The All4779 protein was overexpressed in trans from the plasmid pMAAll4779 (Table 2, Figure 6A) in the recombinant Anabaena strain, Anall4779 (Table 3).
nounced when exposed to higher doses (1.5 kJ m\(^{-2}\)) of UV-B (Figure 7C), while at lower dose of (0.75 kJ m\(^{-2}\)), that of Alr0088 was more beneficial [14]. AnpAM cells exhibited 50% survival upon exposure to 4 μg mitomycinC mL\(^{-1}\) for 30 min, which increased to 80% upon overexpression of All4779 in Anaf14779 cells (Figure 3D), comparable to that observed upon overexpression of Alr7579, but lower than that with Alr0088 [14]. Thus, the presence of high levels of All4779 in Anabaena possibly decreased the net damage to DNA, both in terms of single and double stranded breaks as well as formation of DNA adducts, possibly by efficient repair of the damaged DNA. Overexpression of SSB has been shown to be beneficial by aiding DNA repair in E. coli cells [28].

Thus, All4779 is the major typical bacterial SSB of Anabaena 7120 in terms of structural domains, binding to ssDNA and physiological role in DNA repair. The genes coding for the two atypical truncated annotated SSB proteins, Alr0088 and Alr7579 may have arisen due to gene duplication as suggested for PriB, a dimeric protein with only OB-fold and capable of binding ssDNA [31] and may be involved in other functions such as replication and recombination. The unicellular cyanobacterium, Synechocystis PCC6803 has been shown to be naturally transformable with possible involvement of competence proteins, ComA (Sir0197) [32] and ComF (Sir0380) [33]. The orthologs of these genes are also found in Anabaena 7120, annotated as all3087 and al2926 respectively (http://genome.microbebl3.jp/cyanobase/Anabaena), suggesting the possibility of Anabaena being also naturally transformable, though this needs to be ascertained. Thus, as has been observed in case of the naturally transformable B. Subtilis, the naturally C-terminal truncated BsSsb, is involved in competence by protecting the incoming DNA [10,11], a similar role may also be associated with Alr0088 or/and Alr7579, both of which bear moderate homology to BsSsb, though this needs to be ascertained. The acidic tail, characteristic of most SSBs, has been shown to be the site of interaction with DNA repair proteins for E. coli SSB [3]. Owing to the presence of an acidic tail, All4779 upon overexpression offers better protection from DNA-damage when subjected to different DNA-damage-inducing stresses. Based on data presented, we propose that All4779 be re-annotated as the gene coding for typical single stranded DNA binding protein (SSB) and the corresponding ORF be annotated as the ssb gene of Anabaena 7120.
