Reach-Avoid Analysis for Polynomial Stochastic Differential Equations

Bai Xue, Member, IEEE, Naijun Zhan, and Martin Fränzle

Abstract—In this article, we propose a novel semidefinite programming approach that solves reach-avoid problems over open (i.e., not bounded a priori) time horizons for dynamical systems modeled by polynomial stochastic differential equations. The reach-avoid problem in this article is a probabilistic guarantee: we approximate from the inner a \( p \)-reach-avoid set, i.e., the set of initial states guaranteeing with probability larger than \( p \) that the system eventually enters a given target set while remaining inside a specified safe set till the target hit. Our approach begins with the construction of a bounded value function, whose strict \( p \) super-level set is equal to the \( p \)-reach-avoid set. This value function is then reduced to a twice continuously differentiable solution to a system of equations. The system of equations facilitates the construction of a semidefinite program using sum-of-squares decomposition for multivariate polynomials and thus, the transformation of nonconvex reach-avoid problems into a convex optimization problem. We would like to point out that our approach can straightforwardly be specialized to address classical safety verification by, a.o., stochastic barrier certificate methods and reach-avoid analysis for ordinary differential equations. In addition, several examples are provided to demonstrate theoretical and algorithmic developments of the proposed method.

Index Terms—Inner approximation, reach-avoid analysis, semidefinite programming, stochastic differential equations (SDEs).

I. INTRODUCTION

Reach-avoid analysis combines the construction of safety and specific progress guarantees for dynamical systems, as it addresses guarantees for both the eventual reach of desirable states and avoidance of unsafe states. It is employed in diverse engineering applications including collision avoidance [16] and motion planning [13]. Algorithmic methods for computing reach-avoid guarantees have consequently been widely studied, e.g., in [9], [17], and [30]. In the qualitative setting, reach-avoid analysis generally attempts to determine a set of initial states driving the system to a desirable target set with certainty over either finite time horizons (i.e., given a fixed upper bound on the first hitting time) or open time horizons (i.e., unknown upper bound on the first hitting time) while reliably avoiding a set of unsafe states before hitting the target set. As stochastic processes are central to many phenomena in physics, engineering, biology, and other disciplines [4], [22], when considering stochastic systems, i.e., dynamical systems involving stochastic processes, solving the reach-avoid problem qualitatively in a nonstochastic manner usually gives pessimistic answers, since in general resultant bounds on the values of stochastic inputs will be overly conservative. It indeed is natural to formulate and solve probabilistic variants of reach-avoid problems. The notion of \( p \)-reach-avoid reachability used herein reflects this probabilistic perspective. It requires identifying the set of initial states that guarantee with probability being larger than \( p \) that the dynamical system reaches a given target set safely.

In this article, we investigate the \( p \)-reach-avoid problem for systems modeled by polynomial stochastic differential equations (SDEs) and the focus is on the computation of inner-approximations of the exact \( p \)-reach-avoid set over open time horizons. The \( p \)-reach-avoid set is the set of initial states guaranteeing with probability being larger than \( p \) an eventual hit of a desirable target set while staying inside a designated safe set prior to hitting the target. The inner-approximation problem is reduced to a semidefinite programming problem in our approach. The construction of the semidefinite program originates from a value function whose strict \( p \) super-level set equals the \( p \)-reach-avoid set. The particular value function is defined based on an appropriately stopped variant of the dynamical process under investigation, and is shown to be the unique twice continuously differentiable solution to an effectively constructed system of equations (if it admits twice continuously differentiable solutions). Based on the obtained system of equations, we further construct a system of inequalities and encode them into semidefinite constraints using the sum-of-squares decomposition for multivariate polynomials. This system of constraints finally results in a semidefinite program whose solution under-approximates the exact \( p \)-reach-avoid set. The performance of the proposed approach is illustrated by several examples.

The main contributions of this work are summarized below.
1) An innovative system of equations is proposed for characterizing the exact \( p \)-reach-avoid set over open time horizons for systems modeled by SDEs. The system of equations plays a fundamental role in our methodology, since it explains the origins of the constructed convex program for inner-approximating the \( p \)-reach-avoid set. Besides, the proposed equations can also be used to construct a set of constraints for addressing the classical safety verification problem of SDEs that can be solved with stochastic barrier certificate methods in [23], as commented in Remark 4.
2) A novel convex programming-based approach is proposed for inner-approximating the \( p \)-reach-avoid set over open time horizons, which solves the complicated nonconvex reachability problem arising in dynamical systems and control theory by solving a single convex program.

I. Related Work

Stochastic barrier certificates are known for studying probabilistic specifications of SDEs in existing literature. In [23] a typical supermartingale was employed as a stochastic barrier certificate followed...
by computational conditions derived from Doob’s martingale inequality [8]. It provides an upper bound on the probability of reaching a set of unsafe states for a stochastic system starting from a set of legal initial states. Recently, via removing the requirement of reaching target sets, the stochastic barrier certificate-based method was extended to cater for upper-bounding the probability of leaving a finite region of state space over a given finite time by leveraging a relaxed formulation termed ε-martingale for locally stable systems in [28], and further extended to the problem of controller synthesis for ensuring that unsafe probability is below a threshold in [25]. The differences between the present work and these works are twofold. One is that the set of permissible initial states is synthesized from the system dynamics and the desired reach-avoid property rather than analyzing a given state set. The other one is that a lower bound on the probability of reaching a specified, considered to be desirable, set of target states is computed in the present work. The method in the present work can nevertheless straightforwardly be modified to also cover extended computation of an upper bound on the probability, as pointed out in Remark 4.

The other method to studying the reach-avoid problem involves establishing a connection with certain partial differential equations. One is the classical Dirichlet methods which encode the probability of hitting the target set safely into a Dirichlet problem [7]. Compared to this method, our proposed equation offers a relaxation of assumptions on hitting time and does not require that the expected time of hitting the target set is finite. For details, please refer to Remark 1. Another method is the Hamilton–Jacobi reachability one. Hamilton–Jacobi reachability method addresses reach-avoid problems by exploiting the link to optimal control through viscosity solutions of Hamilton–Jacobi equations. It extends the use of Hamilton–Jacobi equations, which are widely used in optimal control theory, to perform reachability analysis over both finite time horizons [3] and open time horizons [10]. However, grid-based numeric approaches, e.g., the level set method in [18], are traditionally used to solve these equations, rendering the Hamilton–Jacobi reachability method computationally infeasible for even moderate sized systems. Furthermore, such methods cannot guarantee that the computed result is an outer- or inner-approximation of the reach-avoid set. In [2], the reach-avoid problem was reduced to a problem of solving semicontinuous solutions to some variational inequalities. The lack of continuous solutions is an obstacle to solving these inequalities. In contrast, we propose an innovative system of partial differential equations, which is different from existing Hamilton–Jacobi equations, to characterize reach-avoid sets of SDEs. It facilitates the construction of semidefinite programs, which can be efficiently solved by interior-point methods in polynomial time, for computing guaranteed inner-approximations of reach-avoid sets.

Recently, a moment-based method, which is also a convex programming based method, was proposed for studying reach-avoid problems over finite time horizons for SDEs in [26], and a semidefinite programming method derived from Feynman–Kac formula was proposed for analyzing avoid problems (without the requirement of reaching target sets) over finite time horizons in [14] that is algebraically over- and underapproximating the staying probability in a given safety area. Different from the above two methods, our method in this section addresses the reach-avoid problem over open time horizons rather than finite time horizons.

The rest of this article is organized as follows. Section II introduces stochastic systems and reach-avoid problems of interest. After detailing the derivation of the system of equations for characterizing the p-reach-avoid set in Section III-A, we introduce our semidefinite programming method for inner-approximating the p-reach-avoid set in Section III-B. In Section IV, we demonstrate the performance of our approach on several examples. Finally, Section V concludes the article.

II. PRELIMINARIES

We start our exposition by formally presenting polynomial SDEs and p-reach-avoid sets of interest. Beforehand we introduce basic notions used throughout this article: \( \mathbb{R}^{\geq} \) stands for the set of nonnegative reals and \( \mathbb{R} \) for the set of real numbers. For a set \( \Delta, \Delta', \Delta_0, \text{ and } \partial \Delta \) denote the complement, the closure, and the boundary of the set \( \Delta \), respectively. \( \wedge \text{ and } \vee \) denote the logical operation of conjunction and disjunction, respectively. \( \mathbb{R}[\cdot] \) denotes the ring of polynomials in variables given by the argument. Vectors are denoted by boldface letters. \( \sum [x] \) is used to represent the set of sum-of-squares polynomials over variables \( x \), i.e.,

\[
\sum [x] = \{ p \in \mathbb{R}[x] \mid p = \sum_{i=1}^{k'} q_i^2, q_i \in \mathbb{R}[x], i = 1, \ldots, k' \}.
\]

Let \( (\Omega, \mathcal{F}, \mathbb{P}) \) be a probability space [20], where \( \Omega \) is the sample space, \( \mathcal{F} \subseteq \mathcal{B}(\Omega) \) is a σ-algebra on \( \Omega \), and \( \mathbb{P} : \mathcal{F} \rightarrow [0, 1] \) is a probability measure on the measurable space \( (\Omega, \mathcal{F}) \). A random variable \( X \) defined on the probability space \( (\Omega, \mathcal{F}, \mathbb{P}) \) is an \( \mathcal{F} \)-measureable function \( X : \Omega \rightarrow \mathbb{R}^n \); its expectation (w.r.t. \( \mathbb{P} \)) is denoted by \( \mathbb{E}[X] \). The support set for a real-valued function \( f : \Delta \rightarrow \mathbb{R} \) is the closure of the subset of \( \Delta \), where \( f \) is nonzero, i.e., \( \text{supp} \, f = \{ x \in \Delta \mid f(x) \neq 0 \} \).

A continuous-time stochastic process is a parameterized collection of random variables \( \{ X(t, w), t \in T \} \), where the parameter space \( T \) can be either the halfline \( \mathbb{R}^{\geq} \) or an interval \([a, b] \). Note that for each \( t \in T \) fixed, we have a random variable \( X(t, \cdot) : \Omega \rightarrow \mathbb{R}^n \). On the other hand, fixing \( w \in \Omega \) we can consider the function \( X(\cdot, w) : T \rightarrow \mathbb{R}^n \), which is called a path of the stochastic process. A collection \( \{ \mathcal{F}_t \mid t \geq 0 \} \) of σ-algebra of sets in \( \mathcal{F} \) is a filtration if \( \mathcal{F}_t \subseteq \mathcal{F}_{t+} \), for \( t, s \in \mathbb{R}^{\geq} \) (intuitively, \( \mathcal{F}_t \) carries the information known to an observer at time \( t \)). A random variable \( \tau : \Omega \rightarrow \mathbb{R}^{\geq} \) is called a stopping time w.r.t. some filtration \( \{ \mathcal{F}_t \mid t \geq 0 \} \) if \{ \tau \leq t \} \in \mathcal{F}_t \) for all \( t \geq 0 \). Note that a constant time is always a stopping time.

We consider stochastic systems modeled by time-homogeneous SDEs of the form

\[
dX(t, w) = b(X(t, w))dt + \sigma(X(t, w))dW(t, w), t \geq 0 \tag{1}
\]

where \( X(\cdot, \cdot) : T \times \Omega \rightarrow \mathbb{R}^n \) is an \( n \)-dimensional continuous-time stochastic process, \( W(\cdot, \cdot) : T \times \Omega \rightarrow \mathbb{R}^m \) is an \( m \)-dimensional Wiener process (standard Brownian motion), the mapping \( b(\cdot) : \mathbb{R}^n \rightarrow \mathbb{R}^n \) is a vector-valued polynomial (i.e., each of its components is a polynomial), and \( \sigma(\cdot) : \mathbb{R}^n \rightarrow \mathbb{R}^{n \times m} \) is a matrix-valued polynomial, i.e., each of its components is a polynomial.

Since each component of both \( b(x) \) and \( \sigma(x) \) is polynomial over \( x \), satisfying locally Lipschitz conditions, then given an initial state \( x_0 \in \mathbb{R}^n \), an SDE of the form (1) has a unique (maximal local) strong solution over some time interval \([0, T(x_0)(w)) \) for \( w \in \Omega \) [Lemma 2.2, [27]], where \( T(x_0)(w) \) is a positive real value. We denote it as \( X^{x_0}(\cdot, w) : [0, T(x_0)(w)) \times \Omega \rightarrow \mathbb{R}^n \), which satisfies the stochastic integral equation

\[
X^{x_0}(t, w) = x_0 + \int_0^t b(X^{x_0}(s, w))ds + \int_0^t \sigma(X^{x_0}(s, w))dW(s, w)
\]

for \( t \in [0, T(x_0)(w)) \).

The infinitesimal generator underlying system (1) is presented in Definition 1.

**Definition 1**: (See [20]) Let \( X^{x}(t, w) \) be a time-homogeneous Itô diffusion given by SDE (1) with initial state \( x \in \mathbb{R}^n \). The infinitesimal generator \( \mathcal{A} \) of \( X^{x}(t, w) \) is defined by

\[
\mathcal{A}f(x) = \lim_{t \to 0} \frac{E[f(X(t, w))] - f(x)}{t}
= \sum_i b_i(x) \frac{\partial f(x)}{\partial x_i} + \frac{1}{2} \sum_{i,j} (\sigma \sigma^\top)(x)_{ij} \frac{\partial^2 f(x)}{\partial x_i \partial x_j} \tag{2}
\]

for any \( f \in \mathcal{C}^2(\mathbb{R}^n) \), where \( \mathcal{C}^2(\mathbb{R}^n) \) denotes the set of twice continuously differentiable functions.
As a stochastic generalization of the Newton–Leibniz axiom, Dynkin’s formula gives the expected value of any suitably smooth function of an Itô diffusion at a stopping time.

**Theorem 1 (Dynkin’s formula, [20]):** Let $X^a(t, w)$ be a time-homogeneous Itô diffusion given by SDE (1) with the initial state $x \in \mathbb{R}^n$. Suppose $\tau$ is a stopping time with $E[\tau] < \infty$, and $f \in C^2(\mathbb{R}^n)$ with compact support. Then

$$E[f(X^a(\tau, w))] = f(x) + E\left[\int_0^\tau Af(x(s, w))ds\right]. \quad (3)$$

In Theorem 1, if we consider a twice continuously differentiable function $f$ defined on a bounded set $B \subseteq \mathbb{R}^n$, i.e., $f(x) \in C^2(B)$, $f$ can be any twice continuously differentiable function $f \in C^2(\mathbb{R}^n)$ without the assumption of compact support. In this case, the support of $f$ is of course, compact, since the support of $f$ is always closed and bounded.

Now, we define the $p$-reach-avoid set, which is a set of initial states such that the stochastic system (1) starting from it will touch a compact target set $T$ in finite time while staying within a bounded and open safe set $X$ preceding the target first hitting time with probability being larger than $p \in (0, 1)$, where

$$T = \{x \in \mathbb{R}^n \mid g(x) \leq 1\} \text{ and } X = \{x \in \mathbb{R}^n \mid h_0(x) < 0\} \quad (4)$$

with $g(x), h_0(x) \in \mathbb{R}[x]$ and $T \subseteq X$.

**Definition 2 (p-Reach-Avoid Set):** The $p$-reach-avoid set $R_{Ap}$ is the set of initial states such that every trajectory of the stochastic system (1) originating in it will enter the target set $T$ at some time $t \in \mathbb{R}_{\geq 0}$ while staying inside the safe set $X$ over the time horizon $[0, t]$ with probability being larger than $p \in (0, 1)$, i.e.,

$$R_{Ap} = \left\{ x \in X \mid \mathbb{P}\left( \exists t \in \mathbb{R}_{\geq 0}, \{X^a(t, w) \in T \mid \forall \tau \in [0, t], X^a(\tau, w) \in X\} \right) > p \right\}. \quad (5)$$

An inner-approximation is a subset of the set $R_{Ap}$.

**III. INNER-APPROXIMATING $p$-REACH-AVOID SETS**

In this section we present our semidefinite programming based approach for inner-approximating the $p$-reach-avoid set $R_{Ap}$. The semidefinite program is constructed via relaxing a system of equations, whose twice continuously differentiable solution is equal to a bounded value function with its strict $p$ super-level set being equal to the $p$-reach-avoid set $R_{Ap}$.

**A. Characterization of $p$-Reach-Avoid Sets**

In this subsection, we introduce a system of elliptic partial differential equations for characterizing the $p$-reach-avoid set.

The derivation of such equations begins with a value function, which is defined by a new stochastic process $(\hat{X}^{\pi_o}(t, w), t \in \mathbb{R}_{\geq 0})$ for $x_0 \in \hat{X}$, which is a stopped process corresponding to $(X^{\pi_o}(t, w), t \in [0, T^{\pi_o}(w)])$ and the set $X \setminus T$, i.e.,

$$\hat{X}^{\pi_o}(t, w) = \begin{cases} X^{\pi_o}(t, w), & \text{if } t < \tau^{\pi_o}(w), \\ X^{\pi_o}(\tau^{\pi_o}(w), w), & \text{if } t \geq \tau^{\pi_o}(w) \end{cases} \quad (6)$$

where $\tau^{\pi_o}(w) = \inf\{t \mid X^{\pi_o}(t, w) \in \partial X \cap X^{\pi_o}(t, w) \in T\}$ is the first time of exit of $X^{\pi_o}(t, w)$ from the open set $X \cap T$. $\tau^{\pi_o}(w)$ is worth remarking here that if the path $X^{\pi_o}(t, w)$ escapes to infinity in finite time, it must touch the boundary of the bounded safe set $X$ and thus, $\tau^{\pi_o}(w) \leq T^{\pi_o}(w)$. The stopped process $\hat{X}^{\pi_o}(t, w)$ inherits the right continuity and strong Markovian property of $X^{\pi_o}(t, w)$. Moreover, the infinitesimal generator corresponding to $\hat{X}^{\pi_o}(t, w)$ is identical to the one corresponding to $X^{\pi_o}(t, w)$ on the set $X \setminus T$ and is equal to zero outside of the set $X \setminus \bar{T}$.

That is, for $v(x) \in C^2(\mathbb{R}^n)$

$$A v(x) = \sum_i b_i(x) \frac{\partial v(x)}{\partial x_i} + \frac{1}{2} \sum_{i,j} (\sigma \sigma^T)_{ij}(x) \frac{\partial^2 v(x)}{\partial x_i \partial x_j} \quad (7)$$

for $x \in X \setminus T$ and $A v(x) = 0$ for $x \in \partial X \cup T$. This will be implicitly assumed throughout this article.

We observe that the set $\hat{X}$ is an invariant set for the stochastic process $\hat{X}^{\pi_o}(t, w)$ with $x_0 \in \hat{X}$.

**Proposition 1:** If $x_0 \in \hat{X}$ and $w \in \Omega$, then $\hat{X}^{\pi_o}(t, w) \in \hat{X}$ for $t \in \mathbb{R}_{\geq 0}$.

The proof of Proposition 1 is shown in Appendix. From the proof of Proposition 1, we conclude that all sample paths of the stochastic process $(\hat{X}^{\pi_o}(t, w), t \in \mathbb{R}_{\geq 0})$ for $x_0 \in \hat{X}$ can be divided into the following three disjoint groups:

1. paths entering $T$ in finite time;
2. paths entering $\partial X$ in finite time;
3. paths staying inside $X \setminus T$ for all time.

Given $x_0 \in \hat{X}$, let $\tau^\pi_T(w)$ be the first hitting time of the target set $T$ for the path $\hat{X}^{\pi_o}(t, w) : \mathbb{R}_{\geq 0} \to \mathbb{R}^n$, i.e.,

$$\tau^\pi_T(w) = \inf\{t \in \mathbb{R}_{\geq 0} \mid \hat{X}^{\pi_o}(t, w) \in T\}. \quad (8)$$

Below, we show that the $p$-reach-avoid set $R_{Ap}$ is equal to the set of initial states such that the first hitting time of the target set $T$ for the stochastic process $(\hat{X}^{\pi_o}(t, w), t \in \mathbb{R}_{\geq 0})$ is less than infinity with probability being larger than $p$.

**Lemma 1:** $R_{Ap} = \{ x \in \hat{X} \mid \mathbb{P}(\tau^\pi_T(w) < \infty) > p\}$, where $R_{Ap}$ is the $p$-reach-avoid set in Definition 2.

**Proof:** The proof is shown in Appendix.

Now, we present the bounded value function $V(x) : \hat{X} \to \mathbb{R}$, which can be regarded as an ergodic occupation measure or “long-run average” (e.g., [1]) and whose strict $p$ super-level set, i.e., $\{x \in \hat{X} \mid V(x) > p\}$, is equal to the $p$-reach-avoid set $R_{Ap}$, as shown in Lemma 2.

**Lemma 2:** $R_{Ap} = \{ x \in \hat{X} \mid V(x) > p\}$, where $V(x) : \hat{X} \to [0, 1]$ is the value function in (6).

**Proof:** The proof is shown in Appendix.

Based on occupation measures, [6] investigated the exit time problem of polynomial SDEs using the so-called Lasserre or moment sum of squares hierarchy [12]. Since $0 \leq V(x) \leq 1, 0 \leq V(x) \leq 1$ for $x \in \hat{X}$ and thus, $V(x)$ is bounded over $\hat{X}$. It is worth remarking here that

$$\lim_{t \to \infty} \mathbb{E}[\mathbb{1}_T(\hat{X}^{\pi_o}(t, w))]$$

and $\mathbb{E}[\mathbb{1}_T(\hat{X}^{\pi_o}(t, w))]$, which can also be justified by Proposition 6 in [2].

**Lemma 3:** $\mathbb{P}(\hat{X}^{\pi_o}(t, w) \in T) = \mathbb{P}(\tau^\pi_T(w) < \infty) > p$.

**Proof:** The proof is shown in Appendix.

From Lemma 2, we conclude that the exact $p$-reach-avoid set can be obtained if the value function $V(x)$ in (6) is computed. However, it is challenging, even impossible to compute it directly since it involves the knowledge of analytical solutions to SDE (1), which cannot be gained generally, especially for nonlinear systems. In order to address this issue, we go further and show that it is the uniquely twice continuously differentiable solution to a system of elliptic partial differential equations (e.g., [5]) if such a solution exists, as formulated in Theorem 2 below. It is worth noting here that the derived system of equations is different from Hamilton–Jacobi equations in [10] or the variational inequalities in [2].

**Theorem 2:** If there exist $v(x) \in C^2(\hat{X})$ and $u(x) \in C^2(\hat{X})$ such that for $x \in \hat{X}$

$$A v(x) = 0,$$
\[ v(x) = 1/\tau(x) + \mathcal{A}u(x) \]  

then, \( v(x) = V(x), \forall x \in \mathcal{X} \) and thus, \( RA_p = \{ x \in \mathcal{X} | v(x) > p \} \), where \( V() : \mathcal{X} \to \mathbb{R} \) is the value function in (6).

Proof: The proof is shown in Appendix.

Remark 1: Let us present another result related to the reach probability of leaving the set \( \mathcal{X} \setminus \mathcal{T} \) through \( \mathcal{T} \). This result can be obtained via Proposition 7.2 in [7].

Let \( v \) be a solution of the Dirichlet problem in the open, bounded domain \( \mathcal{X} \setminus \mathcal{T} \)

\[ \mathcal{A}u(x) = 0, \text{ in } \mathcal{X} \setminus \mathcal{T}, \]

\[ v(x) = 1, \quad \text{in } \mathcal{T}, \]

\[ v(x) = 0, \quad \text{in } \partial \mathcal{X}, \]

and let \( \tilde{T}(w) = \inf \{ t \geq 0 \mid \tilde{X}^x(t, w) \in \partial \mathcal{T} \cup \partial \mathcal{X} \} \).

\[ E[\tilde{T}(w)] < \infty, \forall x \in \mathcal{X} \setminus \mathcal{T} \]

then, we have \( v(x) = E[1_{\tilde{T}(\tilde{X}^x(t, w))}], x \in \mathcal{X} \setminus \mathcal{T} \) which is the probability of leaving \( \mathcal{X} \setminus \mathcal{T} \) through \( \mathcal{T} \) for the process \( X^x(t, w) \).

Under the condition that \( E[\tilde{T}(w)] < \infty, \forall x \in \mathcal{X} \setminus \mathcal{T} \), which implies that \( E[\tilde{T}(w)] < \infty, \forall x \in \mathcal{X} \setminus \mathcal{T} \), we have \( v(x) = V(x), V(x) \in \mathcal{X} \setminus \mathcal{T} \) and thus, \( \{ x \in \mathcal{X} | v(x) > p \} \) is \( RA_p \). However, when there exists \( x_0 \in \mathcal{X} \) such that \( E[\tilde{T}(w)] = \infty \), we cannot obtain that \( v(x_0) = V(x_0) \). Consequently, \( \{ x \in \mathcal{X} | v(x) > p \} \) may not be an inner-approximation of \( \mathcal{X} \setminus \mathcal{T} \) for all the time with probability being larger than \( p \), but will reach \( \mathcal{T} \) in finite time with probability being smaller than or equal to \( p \).

In contrast, when relating (7) and (8) to the set \( RA_p \), Theorem 2 does not impose \( E[\tilde{T}(w)] = \infty, \forall x \in \mathcal{X} \setminus \mathcal{T} \). Thus, Theorem 2 applies to the case with \( E[\tilde{T}(w)] = \infty \), and thus, is more general. Let us further compare (7) and (8) with (9). We first reformulate (7) and (8) in the following equivalent form:

\[ \mathcal{A}u(x) = 0, \text{ in } \mathcal{X} \setminus \mathcal{T}, \]

\[ v(x) = 1, \quad \text{in } \mathcal{T}, \]

\[ v(x) = 0, \quad \text{in } \partial \mathcal{X}, \]

\[ v(x) = \mathcal{A}u(x), \quad \text{in } \mathcal{X} \setminus \mathcal{T}. \]

(11)

It is easy to find that (7) and (8) have an additional constraint \( v(x) = \mathcal{A}u(x), \text{ in } \mathcal{X} \setminus \mathcal{T} \) comparing with (9). If \( E[\tilde{T}(w)] < \infty, \forall x \in \mathcal{X} \setminus \mathcal{T} \), this constraint is redundant and can be removed, thus turning (11) into (9). In this case, according to Dynkin’s formula in Theorem 1, \( u(x) \) can take

\[ u(x) = E \left[ u(\tilde{X}^x(\tilde{T}(w), \xi)) - \int_0^{\tilde{T}(w)} v(\tilde{X}^x(s, \xi)) ds \right]. \]

Otherwise, this constraint cannot be removed and its existence guarantees that \( \{ x \in \mathcal{X} | v(x) > p \} = RA_p \).

From Theorem 2, we have that if we obtain a twice continuously differentiable solution \( (v(x), u(x)) \) to (7) and (8), the exact \( p \)-reach-avoid set \( RA_p = \{ x \in \mathcal{X} | v(x) > p \} \) can be guaranteed. However, due to the existence of the indicator function \( 1_{\mathcal{T}}(x) \) in (8), we have \( \lim_{x \to \partial \mathcal{X}} [x] = \mathcal{A}u(x_0) \), which is not equal to \( v(x_0) = 1 + \mathcal{A}u(x_0) \), where \( x_0 \in \partial \mathcal{T} \) thus the system of (7) and (8) does not admit twice continuously differentiable solutions \( (v(x), u(x)) \).

Let us take an extreme case: \( b(x) = 0 \) for \( x \in \mathbb{R}^n \) and \( \sigma(x) = 0 \) for \( x \in \mathbb{R}^n \). We obtain that if \( v(x) \) is a solution to the system of (7) and (8), then \( v(x) = 1 \) for \( x \in \mathcal{X} \setminus \mathcal{T} \) and \( v(x) = 0 \) for \( x \in \mathcal{X} \setminus \mathcal{T} \), which implies \( v(x) \notin C^2(\mathcal{X}) \). Despite this, the system of inequalities (7) and (8) plays a fundamental role in our method for inner-approximating the \( p \)-reach-avoid set. In the subsequent subsection, we will relax (7) and (8) into a system of inequalities for inner-approximating the \( p \)-reach-avoid set and solve it efficiently using a semidefinite programming method.

\[ \text{B. Semidefinite Programming Implementation} \]

In this subsection, a semidefinite programming method is presented for inner-approximating the \( p \)-reach-avoid set \( RA_p \). First, we show that an inner-approximation could be obtained via solving a system of inequalities, which is derived from (7) and (8).

Corollary 1: If there exist functions \( v(x) \in C^2(\mathcal{X}) \) and \( u(x) \in C^2(\mathcal{X}) \) such that for \( x \in \mathcal{X} \)

\[ \mathcal{A}u(x) \geq 0, \]

\[ 1/\tau(x) + \mathcal{A}u(x) \geq v(x) \]

then, \( \{ x \in \mathcal{X} | v(x) > p \} \subseteq RA_p \) is an inner-approximation of the \( p \)-reach-avoid set \( RA_p \).

Proof: The proof is shown in Appendix.

Remark 2: Although (7) and (8) do not admit twice continuously differentiable solutions in general, the system of inequalities (12) and (13) does. The pair that \( v(x) \equiv 0 \) and \( u(x) \equiv 0 \) for \( x \in \mathcal{X} \) satisfies the system of inequalities (12) and (13).

Corollary 1 expresses that an inner-approximation of the \( p \)-reach-avoid set \( RA_p \) is provided by a solution \( v(x) \in C^2(\mathcal{X}) \) to constraints (12) and (13). Below, we present a convex programming method for solving constraints (12) and (13).

The equivalent constraints without indicator functions of constraints (12) and (13) are formulated below as follows:

\[ \{ [\mathcal{A}u(x) \geq 0, V(x) \in \mathcal{X} \setminus \mathcal{T}] \} \]

\[ \{ -(v(x) - 1 + \tau(x)) + \mathcal{A}u(x) \geq 0, \forall x \in \mathcal{X} \} \]

which is further equivalent to

\[ \{ \mathcal{A}u(x) \geq 0, V(x) \in \mathcal{X} \setminus \mathcal{T}, -v(x) + \mathcal{A}u(x) \geq 0, \forall x \in \mathcal{X} \setminus \mathcal{T}, -v(x) \geq 0, \forall x \in \partial \mathcal{X}, 1 - v(x) \geq 0, \forall x \in \mathcal{T} \}. \]

If functions \( v(x) \) and \( u(x) \) in (15) are further restricted to polynomial functions over \( x \in \mathbb{R}^n \), we can encode the system of inequalities (15) in the form of sum-of-squares constraints, finally resulting in a semidefinite program (16) for inner-approximating the \( p \)-reach-avoid set \( RA_p \).

\[ \text{max } c \cdot \bar{w} \]

s.t.

\[ \mathcal{A}u(x) + s_0(x)h_0(x) + s_1(x)(1 - g(x)) \in \sum[x], \]

\[ -v(x) + \mathcal{A}u(x) + s_2(x)h_0(x) + s_3(x)(1 - g(x)) \in \sum[x], \]

\[ -v(x) + p(x)h_0(x) \in \sum[x], \]

\[ 1 - v(x) + s_4(x)(g(x) - 1) \in \sum[x] \]

where \( c \cdot \bar{w} = \int_0^t v(x) dx, \bar{w} \) is the constant vector computed by integrating the monomials in \( v(x) \in \mathbb{R}[x] \) over \( \mathcal{X} \), \( c \) is the vector composed of unknown coefficients in \( v(x) \in \mathbb{R}[x] \); \( u(x) \in \mathbb{R}[x] \), and \( s_i(x) \in \sum[x], i = 0, \ldots, 4 \).
The conclusion can be obtained by following the proof of Corollary 1 by removing the expectation operators, we obtain

\[ \forall t \in T, \exists x_0 \in X \mid x(t) \leq 0.5 \text{-reach-avoid set}, \forall x \in A \text{ and } \forall x \in \mathcal{X} \backslash T, \]

\[ \mathcal{A}_u(x) \leq 0, \forall x \in \mathcal{X}. \]

Comparing the set of constraints (21) and constraints (26)–(29) in [23], the main difference between them lies in that the former uses \( \mathcal{A}_u(x, y) \), \( \forall x \in \mathcal{X} \) \( \backslash \mathcal{T} \) rather than \( v(x) \geq 0, \forall x \in \mathcal{X} \) \( \text{it implies } v(x) \geq 0, \forall x \in \partial \mathcal{A} \). Thus, the set of constraints (21) is more expressive than constraints (26)–(29) in [23], which is a special instance of the set of constraints (21) with \( u(x) \equiv 0 \) for \( x \in \mathcal{X} \).

**IV. EXAMPLES**

In this section, we demonstrate on several examples the performance of our approach exploiting semidefinite programming. All computations solving (16) were performed on an i7-7500U 2.70 GHz CPU with 32-GB RAM running Windows 10, where the sum-of-squares module of YALMIP [15] was used to transform the sum-of-squares optimization problem (16) into a semidefinite program and the solver MOSEK [19] was used to solve the resulting semidefinite program. The parameters controlling the performance of our semidefinite programming approach are presented in Table I.

**Example 1 (Population growth):** Consider the stochastic system

\[ dX(t, w) = b(X(t, w))dt + \sigma(X(t, w))dW(t, w) \]

with \( b(X(t, w)) = -X(t, w) \) and \( \sigma(X(t, w)) = \frac{dX(t, w)}{X(t, w)} \), which is a stochastic model of population dynamics subject to random fluctuations that can be attributed to extraneous or chance factors such as the weather, location, and the general environment.

**Table I**

| Parameters of Our Implementations on (16) for Examples 1–3. | d \( x \), d \( u \), d \( \sigma \), \( \mathcal{T} \) | SECONDS |
|-------------------------------------------------------------|---------------------|----------|
| \( x_1 \), \( x_2 \) | 1                   | 1.78     |
| \( x_1 \) | 2                   | 3.78     |
| \( x_1 \) | 3                   | 8.27     |

According to Corollary 2, the safety verification problem can be encoded into the problem of solving the following constraints:

\[ v(x) \leq p, \forall x \in \mathcal{X}, \]

\[ v(x) > 1, \forall x \in \mathcal{T}. \]

\[ v(x) \geq \mathcal{A}_u(x), \forall x \in \mathcal{X} \backslash \mathcal{T}, \]

\[ \mathcal{A}_v(x) \leq 0, \forall x \in \mathcal{X}. \]

\[ v(x) \geq 0, \forall x \in \partial \mathcal{X}. \]

(21)

### IV. Examples

In this section, we demonstrate on several examples the performance of our approach exploiting semidefinite programming. All computations solving (16) were performed on an i7-7500U 2.70 GHz CPU with 32-GB RAM running Windows 10, where the sum-of-squares module of YALMIP [15] was used to transform the sum-of-squares optimization problem (16) into a semidefinite program and the solver MOSEK [19] was used to solve the resulting semidefinite program. The parameters controlling the performance of our semidefinite programming approach are presented in Table I.

**Example 1 (Population growth):** Consider the stochastic system

\[ dX(t, w) = b(X(t, w))dt + \sigma(X(t, w))dW(t, w) \]

where \( b(X(t, w)) = -X(t, w) \) and \( \sigma(X(t, w)) = \frac{dX(t, w)}{X(t, w)} \), which is a stochastic model of population dynamics subject to random fluctuations that can be attributed to extraneous or chance factors such as the weather, location, and the general environment.

**Suppose that the safe set is** \( \mathcal{X} = \{ x \in \mathbb{R} \mid x^2 - 1 < 0 \} \) **and the target set is** \( \mathcal{T} = \{ x \in \mathbb{R} \mid 100x^2 \leq 1 \} \).

**The computed inner-approximations of 0.9- and 0.5-reach-avoid sets are, respectively, illustrated in Figs. 1 and 2, which also shows the computed function \( v(x) \) via solving the semidefinite program (16).**

For gauging the quality of the computed inner-approximations, the 0.9- and 0.5-reach-avoid sets estimated via Monte-Carlo methods are also presented in Figs. 1 and 2, respectively, for comparisons.

**Example 2 (Harmonic oscillator):** Consider a 2-D harmonic oscillator with noisy damping

\[ dX_1(t, w) = \zeta X_2(t, w)dt, \]

\[ dX_2(t, w) = (-\zeta X_1(t, w) - kX_2(t, w))dt - \sigma X_2(t, w)dW(t, w) \]

with \( \zeta = 1, k = 7 \) and \( \sigma = 2 \).

**Suppose that the safe set and the target set are** \( \mathcal{X} = \{ (x_1, x_2) \in \mathbb{R}^2 \mid x_1^2 + x_2^2 < 1 < 0 \} \) **and** \( \mathcal{T} = \{ (x_1, x_2) \in \mathbb{R}^2 \mid 10x_1^2 + 10x_2^2 < 1 \} \), respectively.

**The computed value function** \( v(x_1, x_2) \) **via solving the semidefinite program (16) is shown in Fig. 3 and the corresponding computed 0.9- and 0.9-reach-avoid sets are illustrated in Fig. 4. Two trajectories starting from** \((0.8, 0.0)\) **and** \((-0.9, 0.0)\) **, respectively, are also illustrated.
Fig. 1. Illustration of inner-approximating the reach-avoid set $RA_p$ for Example 1. (Red curve denotes level sets of $v(x)$ computed by solving (16). The set of states between the two dashed blue lines is an inner-approximation of the 0.9-reach-avoid set. The set of green states is the 0.9-reach-avoid set estimated via Monte-Carlo methods.)

Fig. 2. Illustration of inner-approximating the reach-avoid set $RA_p$ for Example 1. (Red curve denotes level sets of $v(x)$ computed by solving (16). The set of states between the two dashed blue lines is an inner-approximation of the 0.5-reach-avoid set. The set of green states is the 0.5-reach-avoid set estimated via Monte-Carlo methods.)

Fig. 3. Illustration of the computed $v(x_1,x_2)$ for Example 2.

in Fig. 4. Also, we use the Monte-Carlo simulation method to assess the quality of computed inner-approximations, which is demonstrated in Fig. 5

Example 3: As a model for the horizontal slow drift motions of a moored floating platform or ship responding to incoming irregular waves John Grue introduced the equation

$$
\ddot{x}_t + a_0 \dot{x}_t + \omega^2 x_t = (T_0 - \alpha_0 \dot{x}_t) \eta W_t
$$

where $W_t$ is 1-D white noise, $a_0$, $w$, $T_0$, $\alpha_0$ and $\eta$ are constants, which can be reduced to the following SDE:

$$
dX_1(t, w) = X_2(t, w) dt
$$

$$
dX_2(t, w) = (-\omega^2 X_1(t, w) - a_0 X_2(t, w)) dt
$$

where $\omega = a_0 = \alpha_0 = \eta = T_0 = 1$.

Suppose that the safe set and the target set are $\mathcal{X} = \{(x_1, x_2)^T \in \mathbb{R}^2 \mid x_1^2 + x_2^2 - 1 < 0\}$ and $\mathcal{T} = \{(x_1, x_2)^T \in \mathbb{R}^2 \mid 4(x_1 - 0.2)^2 + 4(x_2 - 0.2)^2 \leq 1\}$, respectively.

The computed function $v(x_1,x_2)$ via solving the semidefinite program (16) is shown in Fig. 6 and the computed 0.1- and 0.5-reach-avoid sets are illustrated in Fig. 7. Three trajectories starting from $(-0.5, 0.0)$, $(-0.1, -0.5)$, and $(0.1, 0.9)$, respectively, are also illustrated in Fig. 7. Also, we use the Monte-Carlo simulation method to
Appendix

A. The Proof of Proposition 1

Proof: Clearly, if \( x_0 \in \mathcal{T} \cup \partial \mathcal{X} \), we have

\[
\hat{X}^{x_0}(t, w) \in \mathcal{T} \cup \partial \mathcal{X} \quad \forall t \in \mathbb{R}_{\geq 0}.
\]

If \( x_0 \in \mathcal{X} \setminus \mathcal{T} \), one of the following three cases hold:

1) there exists \( t \in \mathbb{R}_{\geq 0} \) such that \( \forall \tau \in [0, t), \hat{X}^{x_0}(\tau, w) \in \mathcal{X} \setminus \mathcal{T} \);

2) there exists \( t \in \mathbb{R}_{\geq 0} \) such that \( \forall \tau \in [0, t), \hat{X}^{x_0}(\tau, w) \in \mathcal{X} \setminus \mathcal{T} \); and

3) \( \hat{X}^{x_0}(t, w) \in \mathcal{X} \setminus \mathcal{T} \) for \( t \in \mathbb{R}_{\geq 0} \) holds.

Therefore, the conclusion holds.

B. The Proof of Lemma 1

Proof: According to Proposition 5 in [2], we have \( \mathbb{P}(\hat{\tau}^p(w) < \infty) = \mathbb{P}(\exists t \in \mathbb{R}_{\geq 0}, \hat{X}^x(t, w) \in \mathcal{T}) \). According to the relationship between stochastic processes \( (\hat{X}^x(t, w), t \in [0, \infty)) \) and \( \{X^x(t, w), t \in [0, T^p(w))\} \), we have that \( \mathbb{P}(\exists t \in \mathbb{R}_{\geq 0}, \hat{X}^x(t, w) \in \mathcal{T}) = \mathbb{P}(\exists t \in \mathbb{R}_{\geq 0}, \hat{X}^x(t, w) \in \mathcal{T} \mid \forall \tau \in [0, t], X^x(\tau, w) \in \mathcal{X}) \).

Therefore, \( RA_p = \{x \in \mathcal{R} \mid \mathbb{P}(\hat{\tau}^p(w) < \infty) > p\} \).

C. The Proof of Lemma 2

Proof: According to Lemma 1, we just need to prove that \( V(x) = \mathbb{P}(\hat{\tau}^p(w) < \infty) \).

For \( t \in \mathbb{R}_{\geq 0} \), according to Fubini’s theorem [24], we have

\[
E \left[ \int_0^t 1_{\mathcal{T}}(\hat{X}^x(t, w)) \, d\tau \right] = \int_0^t E \left[ 1_{\mathcal{T}}(\hat{X}^x(t, w)) \right] \, d\tau.
\]

Therefore, \( V(x) = \lim_{t \to \infty} \int_0^t E \left[ 1_{\mathcal{T}}(\hat{X}^x(t, w)) \right] \, d\tau \). According to Lemma 3 shown below, we have \( \lim_{t \to \infty} \mathbb{P}(\hat{X}^x(t, w) \in \mathcal{T}) = \mathbb{P}(\hat{\tau}^p(w) < \infty) \). As a consequence, \( V(x) = \mathbb{P}(\hat{\tau}^p(w) < \infty) \).

Thus, \( RA_p = \{x \in \mathcal{R} \mid V(x) > p\} \) from Lemma 1.

D. The Proof of Lemma 3

Proof: According to Corollary 1 in [29] stating that \( \mathbb{P}(\exists t \in \mathbb{R}_{\geq 0}, \hat{X}^{x_0}(t, w) \in \mathcal{T}) = \lim_{t \to \infty} \mathbb{P}(\hat{X}^{x_0}(t, w) \in \mathcal{T}) \), and Proposition 5 in [2] stating that \( \mathbb{P}(\hat{\tau}^p(w) < \infty) = \mathbb{P}(\exists t \in \mathbb{R}_{\geq 0}, \hat{X}^{x_0}(t, w) \in \mathcal{T}) \), we have the conclusion.

E. The Proof of Theorem 2

Proof: Let \( x \in \mathcal{R} \). According to Proposition 1, we have that \( \hat{X}^x(t, w) \in \mathcal{R} \) for \( t \in \mathbb{R}_{\geq 0} \) and \( w \in \Omega \).

From (7) and Theorem 1, together with the fact that any constant time \( t \in \mathbb{R}_{\geq 0} \) is a stopping time with \( E[t] < \infty \), we have

\[
v(x) = E \left[ v\left(\hat{X}^x(t, w)\right) \right], \forall t \in \mathbb{R}_{\geq 0}.
\]

From (8), we have that for \( t \in \mathbb{R}_{\geq 0} \)

\[
v\left(\hat{X}^x(t, w)\right) = 1_{\mathcal{T}}(\hat{X}^x(t, w)) + \mathcal{A}u\left(\hat{X}^x(t, w)\right).
\]

From (23), we have that for \( t \in \mathbb{R}_{\geq 0}, E \left[ \int_0^t v\left(\hat{X}^x(s, w)\right) \, ds \right] = E \left[ \int_0^t 1_{\mathcal{T}}\left(\hat{X}^x(s, w)\right) \, ds \right] + E \left[ \int_0^t \mathcal{A}u\left(\hat{X}^x(s, w)\right) \, ds \right] \)

V. CONCLUSION

We have exposed and proved a correct algorithm based on semidefinite programming facilitating inner-approximations of \( p \)-reach-avoid sets of systems modeled by polynomial SDEs over open time horizons. As the \( p \)-reach-avoid set is the set of initial states forcing the system, with sufficient probability being larger than \( p \), to eventually reach a desired target set while satisfying certain legal state constraints till the first hit time, it is of immediate interest in the design of reliable systems. The benchmark examples exposed in the previous section give an idea of the design or analysis obligations that can be answered by computation of safe, i.e., inner approximations of \( p \)-reach-avoid sets. They also demonstrate the performance of the proposed approach.
further according to Fubini’s theorem \[24\] \[
\int_0^t E \left[ v \left( \bar{X}^w (s, w) \right) \right] \, ds = E \left[ \int_0^t 1_T \left( \bar{X}^w (s, w) \right) \, ds \right]
\]
holds. Consequently, \[v(\bar{x}) = E \left[ \int_0^T 1_T \left( \bar{X}^w (s, w) \right) \, ds \right] + \left. \left( \int_0^T v \left( \bar{X}^w (s, w) \right) \, ds \right) \right|_{t=0}^{t=T} + E \left( u \left( \bar{x} (t, w) \right) \right) \]
\end{equation}
\[\forall t \in \mathbb{R}_{\geq 0}. \]

Since \( u(\bar{x}) \) is continuously differentiable over \( \mathcal{X} \), it is bounded over \( \bar{x} \in \mathcal{X} \). Consequently, \( v(\bar{x}) \) is

further that \( RA_p = \{ x \in \mathcal{X} | v(x) > p \} \) from Lemma 2.

F. The Proof of Corollary 1

Proof: According to Proposition 1

Further, \( \bar{X} \) satisfies constraints in \(16\) and \( \partial \mathcal{X} \subseteq \{ x \in \mathbb{R}^n \} \) holds. We have \( v(x) \) satisfies (15). Thus, \( \{ x \in \mathcal{X} | v(x) > p \} \subseteq RA_p \) holds from Corollary 1.
