Abstract
Phytopathogens and herbivores induce plant defences. Whereas there is evidence that some pathogens suppress these defences by interfering with signalling pathways involved in the defence, such evidence is scarce for herbivores. We found that the invasive spider mite Tetranychus evansi suppresses the induction of the salicylic acid and jasmonic acid signalling routes involved in induced plant defences in tomato. This was reflected in the levels of inducible defence compounds, such as proteinase inhibitors, which in mite-infested plants were reduced to even lower levels than the constitutive levels in herbivore-free plants. Additionally, the spider mite suppressed the release of inducible volatiles, which are implicated in plant defence. Consequently, the mites performed much better on previously attacked plants than on non-attacked plants. These findings provide a new perspective on plant–herbivore interactions, plant protection and plant resistance to invasive species.

Keywords
Defence suppression, induced plant defence, jasmonic acid, plant volatiles, plant–herbivore interaction, predatory mites, proteinase inhibitors, salicylic acid, spider mites, Tetranychus evansi.

INTRODUCTION
Plant defences can be induced by antagonists such as pathogens (Dangl & Jones 2001) and herbivores (Walling 2000). The molecular mechanisms involved in these defences are being elucidated rapidly (Kessler & Baldwin 2002; De Vos et al. 2005; Kant & Baldwin 2007; Pieterse & Dicke 2007). Induced plant defences critically depend on the detection and recognition of their attackers (Wu & Baldwin 2009), and one strategy for pathogens and herbivores to circumvent defences is to avoid being detected and feed stealthily (Walling 2008). The complex biochemical pathways involved in induced plant defence (Walling 2000) offer another way to elude defences; such pathways may be vulnerable to manipulation by pathogens (Nomura et al. 2006; McDowell & Simon 2008) and herbivores (Pieterse & Dicke 2007; Zarate et al. 2007). As a result of this manipulation, attacked plants may become even better resources for the pathogens and herbivores than non-damaged plants. Although such herbivore-induced susceptibility has often been suggested (Karban & Baldwin 1997), there is surprisingly little evidence for it. Earlier studies (for references, see Karban & Baldwin 1997) show increased herbivore attack of previously damaged plants, but the previous damage was often artificial and most of these studies did not measure herbivore performance, but preference.

Recently, some more convincing examples have been published. For example, glucose oxidase in caterpillar saliva reduces induced defences (Musser et al. 2002; Bede et al. 2006), and attacks by Colorado potato beetles suppress transcription of genes encoding for proteinase inhibitors (PI) involved in plant defence (Lawrence et al. 2008). None of these examples, however, has shown the effects of defence suppression on herbivore performance, and it has been suggested that suppression could even benefit the plant rather than the herbivore (Kahl et al. 2000). Other studies show that plants become more susceptible to attacks by herbivores after previous attacks by other species of herbivores (Saige et al. 2006; Poelman et al. 2008). In these cases, trade-offs between defence types against different herbivore species may be involved (via so-called antagonistic cross-talk between signalling pathways involved in plant defence, Thaler 1999; see Bruessow et al. 2010 for an example of negative cross-talk within the same species). Herbivores may also vector plant pathogens, thereby inducing plant defences against pathogens, which in turn negatively affect the defences against herbivores (Belliure et al. 2005). In conclusion, examples of herbivore attacks that increase plant quality for conspecifics are scarce and the effects reported so far are small (Gonzales et al. 2002; Saige et al. 2006; Bruessow et al. 2010). Thus, there is still little evidence for manipulation of plant defences by herbivores.

Recently, we showed that one population of a generalist herbivore, the spider mite Tetranychus urticae, harbours variation in its ability to suppress the induced defences of tomato plants to lower levels (Kant et al. 2008). This suppression had a small, but significant, positive effect on the fitness of non-suppressing mites residing on the same leaflet (Kant et al. 2008). Here, we report on a closely related mite species, Tetranychus evansi, which reduces induced tomato defences so severely that these drop even below house-keeping levels. Both T. evansi and T. urticae attack and eventually kill tomato plants, not because of high per capita consumption rates of individual mites, but...
due to their high population growth rates. Until the 1970s, the distribution of T. evansi was restricted to South America, where it attacks solanaceous plants, including tomato but then spread to Africa and Mediterranean Europe, where it now poses a serious threat to tomato crops, as it cannot be controlled by commercially available predators. We evaluated the performance of T. evansi on plants previously attacked by conspecifics and by T. urticae and the effect of these two species on induced plant defences. Specifically, we consider direct plant defences (i.e. defences that directly affect the performance of herbivores) and indirect defences (i.e. the attraction of natural enemies of the herbivores through the production of volatiles). We investigated the involvement of the two main signal-transduction pathways involved in plant defences.

MATERIAL AND METHODS

Rearing methods

Tomato seeds (Solanum lycopersicum var Santa Clara I-5300) were sown in trays in a commercial substrate composed of vermiculite and organic fertilizer, and kept inside mite-proof screen cages in a greenhouse. Plants (21 days old) were transferred to plastic pots (2 L) that contained a mixture of soil plus bovine manure (3 : 1) and fertilizer (4-14-8 N-P-K). Tomato plants were further grown in mite-proof screen cages in a greenhouse until they were 45 days old and had at least four completely developed leaves. Subsequently, plants were used either for the experiments or for spider mite rearing.

Spider mites (T. evansi and T. urticae) were obtained in 2002 from naturally infested tomato plants of the same variety mentioned above, in a greenhouse at the Federal University of Viçosa, Brazil. Both species were cultured on detached tomato leaves, of which the petiole was inserted in a PVC tube with water to maintain leaf turgor. Tubes with infested leaves were kept in PVC trays filled with detergent and water (1 : 25, v/v), which served to prevent mite escapes and invasion of mites and other arthropods. The mass culture was maintained at 25 ± 3 °C, 70–90% relative humidity (RH) and 12 h light. A culture of the predatory mite Phytoseius longipes was started in 2006 with individuals that were provided by Dr Gilberto de Moraes (USP São Paulo, Brazil). Colonies were maintained at 28 ± 2 °C; 80 ± 10% RH; 12 h light, supplied with detached tomato leaves from the T. evansi culture. A culture of another predatory mite species, Phytoseius macropilis, was started with specimens collected from lima bean plants infested with two-spotted spider mites in a greenhouse at the Federal University of Viçosa, Brazil. The mites were subsequently reared on detached tomato leaves infested with T. urticae, under identical conditions as above.

Performance

Adult female spider mites produce 50–70% of their body weight in eggs per day, whereas juveniles increase much < 50% in weight per day. Hence, conversion of food is highest in adult females, and the rate of oviposition is so strongly related to population growth rate that it is a reasonable stand-in measure for fitness in local populations (Sabelis 1991). Furthermore, inferior host plant quality results in lower oviposition rates per plant among treatments were tested with a linear mixed effects (lme) model on ln(x + 1) transformed numbers of eggs with female and plant as a random factor. Differences in survival and the number of mites escaped were compared among treatments with a generalized linear model (GLM) with a binomial error distribution. Note that the experiments with T. urticae and T. evansi, as well as those on PI and volatile analysis could not be carried out at the same time for logistical reasons. As it was impossible to maintain constant greenhouse conditions, plant quality may have varied with time. Treatments could therefore only be compared with their controls within the same experiment.

Juvenile development was measured on similarly prepared leaf discs (10 discs of four plants of each treatment and of eight control plants), on which one egg from a cohort of eggs was placed. Survival and development were monitored twice per day until all individuals had either died or matured. Data were subjected to a Kaplan–Meier survival analysis (Hosmer & Lemeshow 1999). Log-rank tests were used for pairwise planned comparisons (Hosmer & Lemeshow 1999).

Proteinase inhibitor assays

Proteinase inhibitors are involved in induced plant defence. They are induced by herbivore attacks and hamper the action of digestive proteinases present in the herbivore gut (Koiwa et al. 1997), including those of spider mites (Li et al. 2002a; Kant et al. 2004). Proteinase inhibitor activity was measured in non-damaged and damaged leaves of plants treated as in the oviposition experiments as well as in non-damaged plants (N = 4 plants). An amount of 600 mg of leaf tissue was frozen in liquid nitrogen and stored at −80 °C. Subsequently, it was ground in liquid nitrogen and homogenized in 1000 µL extraction buffer (0.1 M Tris-HCl buffer, pH 8.2 and 20 mM CaCl₂ : 1 : 3 w/v), centrifuged at 17 200 g (30 min, 4 °C). Fifty µL trypsin (4.7 × 10⁻⁵ M) was mixed with 50 µL of the supernatant and 500 µL extraction buffer (0.1 M Tris-HCl buffer, pH 8.2 and 20 mM CaCl₂), and was incubated at room temperature for 5 min. Controls consisted of 500 µL extraction buffer and 50 µL of trypsin (4.7 × 10⁻⁵ M). A 500 µL aliquot of the mixture was added to 500 µL extraction buffer and 500 µL Na-Benzoyl-D,L-arginine
4-nitroanilide hydrochloride (1.2 mM). Trypsin activity was monitored with a spectrophotometer (410 nm). The difference between the absorbance measured at 150 and 60 s was used to determine trypsin activity. Measurements were performed in triplicate per sample, and were converted to μg trypsin inhibited per gram of protein (Kant et al. 2004) and were corrected for the dilution (Kakade et al. 1974). Differences among treatments were tested with an lme model with replicate as a random factor.

**Gene expression**

The induction of PI genes such as *WIPI-II* and downstream protein activity depends on the jasmonic acid (JA) signal-transduction pathway, which is mainly activated after attacks by herbivores and necrotrophic pathogens (Walling 2000; De Vos et al. 2005; Zarate et al. 2007). However, attacks of herbivores like whiteflies, aphids and spider mites can also activate the salicylic acid (SA) pathway (Walling 2000; Kant et al. 2004; De Vos et al. 2005). To verify which defensive pathways were affected by *T. evansi*, we measured the expression of the genes *WTIP-II, PR-P6* and *GGPS1*. The induction of *WTIP-II* is both dependent on the biosynthesis (Li et al. 2002b) and on perception of JA (Li et al. 2004) and is a direct indicator of the JA response. The tomato *PR-P6* gene is a pathogenesis-related protein, induced by SA (Ament et al. 2006; van Schie et al. 2007b) and a direct indicator of the SA response. *GGPS1* produces the precursor for the volatile homoterpene (E,E)-4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT), which is attractive to predators of spider mites (Kant et al. 2004). This gene is induced by JA, but a basal level of SA is required for its induction (Ament et al. 2006).

Expression analyses were performed on non-damaged leaves and damaged leaves of plants (45 days) infested (7 days) with 200 *T. urticae* or 200 *T. evansi* females as above. Leaflets were cut in small pieces and immediately stored in RNALater® (Applied Biosystems, Foster City, CA, USA) according to the manufacturer’s instructions. Gene specific quantitative RT-PCR primers were designed for the target genes as well as an endogenous control gene Rub 1 conjugating enzyme (RCE1). *WTIP-II* fw: GAC AAG GTA GTA ATC AAT TAT CC; *WTIP-II* rev: GGG CAT ATC CCG AAC CAA GA. *PR-P6* fw: GTC CTT CAT CTT CAT GTT TCC A; *PR-P6* rev: TAG ATA AGT GGT GTA TGT GCC. *RCE* fw: AGT TGC GTC TTC ATA AAG ATA TAA G; *RCE* rev: GAA CGT AAA TGT GGC ACC CTT A. *GGPS1* fw: GGC AGA TGG TGG ACT TGG GCA; *GGPS1* rev: CTC ATT CGC TCC ACA TCA ACC (van Schie et al. 2007a). Total RNA was extracted using the hot phenol method. Purity and integrity was checked by NanoDrop (ND-1000, Thermo-Fisher, Waltham, MA, USA) analyses and agarose-gel electrophoresis (Frost et al. 2002b) and on perception of JA (Li et al. 2004) and is a direct indicator of the JA response. The tomato *PR-P6* gene is a pathogenesis-related protein, induced by SA (Ament et al. 2006; van Schie et al. 2007b) and a direct indicator of the SA response. *GGPS1* produces the precursor for the volatile homoterpene (E,E)-4,8,12-trimethyltrideca-1,3,7,11-tetraene (TMTT), which is attractive to predators of spider mites (Kant et al. 2004). This gene is induced by JA, but a basal level of SA is required for its induction (Ament et al. 2006).

**Host plant selection**

Plants were infested with spider mites as described above (Volatiles analysis). Non-damaged plants of the same age were used as control odour sources. The attraction of individual spider mites and predatory mites to the odours emanating from these plants was assessed using a Y-tube olfactometer (Pallini et al. 1997). Prior to testing, adult female *T. evansi* were starved for 24 h (28 ± 2 °C; 70 ± 10% RH); predators for 3 h. Mites were tested individually in the olfactometer as described in Pallini et al. (1997). Data were analysed with a GLM with a Poisson error distribution (Crawley 2007).

**Number of dispersers**

Populations of *T. evansi* and *T. urticae* grow fast and in the absence of predators eventually over-exploit their host plant, after which the mites disperse to new plants. As result of this metapopulation structure (Ellner et al. 2001), the per capita oviposition rate or
RESULTS

Performance

Tetranychus evansi had a significantly higher oviposition rate on tomato leaves that were previously attacked by conspecifics than on leaves of non-damaged tomato plants or on systemic leaves (i.e. non-attacked leaves from previously attacked plants) (Fig. 1a). Mortality of adult females during the oviposition experiment was significantly lower on leaves previously attacked by T. evansi than on non-attacked leaves (GLM, $\chi^2_{1,10} = 6.27, P = 0.012$), but was not significantly different from that on systemic leaves ($\chi^2_{1,10} = 2.42, P = 0.12$) (average mortality ± SE: non-attacked: 0.389 ± 0.098; systemic: 0.331 ± 0.164; damaged: 0.167 ± 0.047).

The oviposition rate of T. evansi on tomato leaves previously attacked by T. urticae was lower than on non-damaged leaves (Fig. 1b), suggesting that T. evansi is sensitive to defences induced by T. urticae. These results also confirm that the inducible defences in our tomato variety were intact. The mortality of adult T. evansi was significantly higher on leaves damaged by T. urticae than on systemic leaves ($\chi^2_{2,14} = 8.1224, P = 0.0044$) and than on non-attacked leaves ($\chi^2_{2,14} = 28.9, P < 0.0001$) (non-attacked: 0.025 ± 0.016; systemic: 0.125 ± 0.048; damaged: 0.40 ± 0.041). Notice that the experiments with plants attacked by T. urticae and T. evansi were not carried out at the same time for logistical reasons, and plant quality may have varied with time. Oviposition rates and mortality on leaves attacked by T. evansi and T. urticae can therefore not be compared directly, but only with their respective controls.

There was no effect of plant treatment on juvenile survival of T. evansi (Fig. 1c; $\chi^2_4 = 1.6, P = 0.804$), but there was a significant effect on developmental rate (Fig. 1c; $\chi^2_4 = 20.1, P = 0.0005$). This was caused by the developmental rate of juveniles on leaf discs from plants previously attacked by T. urticae being lower than in all other treatments (Fig. 1c, all $P$ values < 0.05).

Proteinase inhibitor assays

Levels of PI activity in leaves attacked by T. evansi were less than half that of activity levels in leaves of non-damaged plants (Fig. 2). PI activity in systemic leaves was higher than in damaged leaves (Fig. 2), but somewhat lower than in non-damaged leaves, suggesting that the effect was, at least partially, systemic. Attacks by T. urticae increased PI activity (Fig. 2), as reported before (Kant et al. 2004), showing that

![Figure 1](image-url) Performance of Tetranychus evansi. Mean (± SEM, four plants, 10 mites per plant) oviposition of T. evansi on tomato leaves that were previously damaged by conspecific mites (a, closed circles, solid line) or Tetranychus urticae (b, closed triangles, solid line), on non-infested leaves of infested plants (systemic, open circles and triangles and interrupted line) and leaves from non-damaged control plants (eight plants, 10 mites per plant, closed squares and dotted line). The effect of treatment was significant (linear mixed effects model; a: $F_{2,11} = 9.85, P = 0.0025$; b: $F_{2,11} = 44.6, P < 0.0001$). Curves with different letters within each panel differ significantly. The experiments with T. urticae and T. evansi were not carried out at the same time for logistical reasons. As it was impossible to maintain constant greenhouse conditions, plant quality will have varied with time. Treatments can therefore only be compared with their controls within the same experiment (i.e. within the same panel). (c) Developmental rate and juvenile survival of T. evansi (in h, from egg to adult) on tomato leaves treated as in a and b. The curves show the fraction of mites of the initial cohort of 40 eggs per treatment that developed into adults. Error bars are left out for reasons of clarity.
induced plant defence through increased PI activity was intact in the tomato plants.

**Gene expression**

*Tetranychus evansi* did not up-regulate WIPI-II (JA pathway) or PR-P6 (SA pathway) (Fig. 3). In contrast, leaves attacked by *T. urticae* showed strongly increased expression of these genes (Fig. 3), confirming earlier results (Kant *et al.* 2004) and demonstrating that normal establishment of induced defences is hampered by *T. evansi*. The GGPS1 gene is involved in indirect plant defence in tomato (Kant *et al.* 2004). Tomato leaves attacked by *T. evansi* showed down-regulation of GGPS1 (Fig. 3). Leaves attacked by *T. urticae* showed the normal up-regulation of GGPS1 relative to un-attacked plants, in agreement with earlier reports (Kant *et al.* 2004) (Fig. 3).

**Volatile analysis**

Two volatiles were emitted in higher amounts by leaves under attack by *T. urticae* than by control leaves (Fig. 4a): TMTT, which is known to be induced by *T. urticae* (Kant *et al.* 2004), and β-myrcene, which also increases upon *T. urticae* infestation, but not always significantly (Kant *et al.* 2004). The two other volatiles shown in Fig. 4, β-caryophyllene and α-copaene, are constitutively produced by tomato plants and not induced by *T. urticae* (Kant *et al.* 2004). In contrast, the emission of

---

**Figure 2** Proteinase inhibitor activity. Mean (+ SEM, *n* = 4 plants) proteinase inhibitor (PI) activity in leaves damaged by *Tetranychus evansi* (a) or *Tetranychus urticae* (b) and non-damaged leaves from similarly damaged plants (systemic) and leaves of non-damaged plants. The effect of treatment was significant (ANOVA on log-transformed relative activity: *F*₃,₁₂ = 25.6, *P* < 0.0001). Within each panel, bars labelled with different letters are significantly different (Tukey HSD). The experiments with *T. urticae* and *T. evansi* were not carried out at the same time for logistical reasons. As it was impossible to maintain constant greenhouse conditions, plant quality will have varied with time. Treatments can therefore only be compared with their controls within the same experiment (i.e. within the same panel).

**Figure 3** Expression of genes regulated by jasmonic acid (JA) or salicylic acid (SA). Mean expression levels normalized to *RCE1* (+ SEM, *n* = 3, two technical replicates) of WIPI-II, PR-P6 and GGPS1 in leaves attacked by *Tetranychus evansi* (white bars), systemic leaves of the same plants (crosshatched bars), leaves attacked by *Tetranychus urticae* (light dotted bars), systemic leaves (dark dotted bars) and leaves of non-attacked plants (black bars). The effect of treatment was significant (MANOVA: Pillai-Bartlett statistic = 1.41, d.f. = 4,13, *P* = 0.0060), as was the effect on each gene separately (ANOVA: WIPI-II: *F*₄,₁₃ = 4.78, *P* = 0.014; PR-P6: *F*₄,₁₃ = 4.67, *P* = 0.015; GGPS1: *F*₄,₁₃ = 6.13, *P* = 0.005). Bars with different letters within each gene differ significantly.

**Figure 4** Production of volatile plant compounds involved in indirect plant defence. Shown are mean (+ SEM) volatile profiles of plants. (a) Plants (*n* = 3) attacked by *Tetranychus urticae* (grey bars) produced more (E,E)-4,8,12-trimethyltetradeca-1,3,7,11-tetraene (TMTT) than non-damaged plants (white bars) (lme, *F*₁,₂ = 34.8, *P* = 0.0275, *** and marginally significantly more myrcene (*F*₁,₂ = 7.75, *P* = 0.108, •). (b) Plants (*n* = 5) attacked by *Tetranychus evansi* (grey bars) and non-attacked plants (white bars) did not differ significantly (lme, all *P* values > 0.17).
volatiles of plants attacked by *T. evansi* was not different from that of non-damaged plants (Fig. 4b). Univariate statistical analysis, an integral part of Metalign, was used for mass peak selection, with 95% significance, to compare the means of each individual aligned mass peak from infested leaves with the controls. Metalign did not identify any fragments that were significantly induced or reduced in leaves attacked by *T. evansi* compared with control leaves (all *P* values > 0.10). Hence, *T. evansi* does not induce the production of the same volatiles as *T. urticae*.

**Host plant selection**

The lack of induction of the production of volatiles by *T. evansi* was further tested through the response of *T. evansi* and two species of predatory mite to the volatiles emitted by plants attacked by *T. evansi* and *T. urticae*. Predatory mites are important natural enemies of spider mites; they are often used to control them and they are attracted to plant volatiles induced by spider mites (Dicke *et al.* 1990), including tomato plants (Kant *et al.* 2004). The two species used here, *P. longipes* and *P. macropilis*, co-occur with *T. evansi* in South America, and *P. longipes*, is considered a potential biological control agent of *T. evansi* (Furtado *et al.* 2007). All three mite species significantly preferred odours of plants with *T. evansi* to those of non-damaged plants, suggesting that the plant–herbivore complex did release attractive odours (Fig. 5). Moreover, *T. evansi* had a clear preference for odours of plants attacked by conspecifics when offered together with odours of plants with *T. urticae* (Fig. 5), confirming that the volatiles emanating from plants with these two closely related spider mites are different. In contrast, *P. longipes* showed no preference for odours of plants with *T. urticae* or *T. evansi* (Fig. 5).

**Number of dispersers**

The effect of reduced plant defences caused by *T. evansi* did not result in more rapid over-exploitation of the host plant compared with the defence-inducing *T. urticae*. In contrast, it ultimately gave rise to higher numbers of mites per plant, hence, higher numbers of dispersers (Fig. 6), which is a stand-in measure for fitness in populations with a metapopulation structure (Metz & Gyllenberg 2001).

**DISCUSSION**

We show that the phytophagous mite *T. evansi* had a higher oviposition rate and a higher adult survival on plants that were previously attacked by conspecifics than on non-damaged plants. These results show that *T. evansi* has a higher performance on plants that were previously attacked by conspecifics. In contrast, *T. evansi* had a lower oviposition rate, lower juvenile and adult survival and a lower juvenile developmental rate on plants that were previously attacked by its congener *T. urticae*. This corresponds to what is normally observed as the effect of induced plant defence; herbivore performance is lower on previously attacked plants than on non-damaged plants (Walling 2000).

The higher oviposition rate of *T. evansi* on previously attacked plants coincided with these plants having lower PI activity. It is known that tomato *def-1* mutants, which are deficient in wound-induced JA accumulation and expression of downstream target genes, do not show increased PI activity upon herbivore attack. However, these *def-1* plants show similar house-keeping levels of PI activity as non-damaged wild-type plants (Li *et al.* 2002a), indicating that constitutive, house-keeping, PI levels are regulated differently than JA-dependent induced PI levels (O’Donnell *et al.* 2003). As the PI activity in plants damaged by *T. evansi* was significantly lower than that in non-damaged plants (Fig. 2), this shows that, unlike other herbivores (Musser *et al.* 2002; Bede *et al.* 2006; Kant *et al.* 2008; Lawrence *et al.* 2008; Walling 2008), *T. evansi* does not just prevent induction of plant defences but reduces house-keeping levels of defence-related plant constituents below the levels in non-attacked plants. This suggests that the mite reduces constitutive plant defences as well.

The low activity of PI in leaves previously attacked by *T. evansi*, in turn, coincided with lack of up-regulation of WTPH-II, a gene that is dependent on the JA defensive pathway, one of the two main signalling routes involved in plant defence in tomato. Likewise, PR-P6, a marker gene of the other main signalling route, the SA pathway, was also not up-regulated by *T. evansi* damage. The fact that marker genes from neither of the two pathways were up-regulated shows that the

---

**Figure 5** Attraction of mites by odours of tomato plants attacked by *Tetranychus evansi*. Bars represent the fraction of mites choosing for the odours of plants attacked by *T. evansi*, a fraction of 0.5 would indicate no preference. Fractions were averaged (+ SEM) over replicates (numbers given inside the bars), carried out using different sets of three plants and different groups of 20 mites. The spider mite *T. evansi* (top bar) and the predatory mites *Phytoseiulus longipes* and *Phytoseiulus macropilis* (second and third bar) preferred odours of plants attacked by *T. evansi* to odours of non-damaged plants. Moreover, *T. evansi* preferred odours of plants attacked by *T. evansi* to odours of plants attacked by *Tetranychus urticae* (fourth bar) and *P. longipes* did not show preference for either odour (lower bar). ****GLM: *P* < 0.001; n.s.: GLM: not significant.

**Figure 6** Population growth rates of *Tetranychus evansi* and *Tetranychus urticae* on intact tomato plants. Shown are mean densities (+ SEM, *n* = 4) of adult female *T. evansi* (closed symbols) and *T. urticae* (open symbols) until the plants were overexploited. Through time, the densities of *T. evansi* were significantly higher than those of *T. urticae* (linear mixed effects model, *χ²* = 116.7, d.f. = 1, *P* < 0.0001).
lack of induction of either of the two pathways was not caused by negative cross-talk between the SA and JA signalling pathways (Thaler 1999; Brussow et al. 2010).

GGPS1 was also not up-regulated in plants attacked by T. evansi, in agreement with the lack of TMPT emission by these plants. Counter to our expectation, T. evansi and two species of predatory mite were more attracted to plants attacked by T. evansi than to non-damaged plants in an olfactometer (Fig. 5), showing that more volatiles or more volatile compounds emanated from the infested plants. The fact that T. evansi prefers odours of plants attacked by conspecifics to plants attacked by T. urticae confirms our finding that the volatiles emanating from plants attacked by these two species differ, but evidently, P. longipes did not discriminate between these volatiles (Fig. 5). Apparently, the volatiles that we identified are not of key importance for the attraction of these natural enemies (see D’Alessandro & Turlings 2005 for a similar case for parasitic wasps). The inducible plant volatiles found here are known to be attractive for other species of predatory mite (Dicke et al. 1990), but may also be involved in other defensive functions (Frost et al. 2007).

The high oviposition rate of T. evansi on tomato plants resulted in a high population growth rate on tomato plants (the local population growth rate estimated from Fig. 6 is 0.300 ± 0.009 day\(^{-1}\)), which is the highest recorded for spider mites at the prevailing temperature (Sabelis 1991). The estimated growth rate of T. urticae (Fig. 6, 0.262 ± 0.005) closely coincided with the average intrinsic growth rate published for this species (0.269 ± 0.020) (Sabelis 1991), showing that our results with the strain of T. urticae and the variety of tomato tested do not differ from earlier reports. The growth rate of T. urticae is generally considered to be among the highest for spider mites, but it was significantly lower than that of T. evansi (t-test, \(t_6 = 3.63, P = 0.012\)), which is striking because tomato is generally considered as a low quality food source for T. urticae (Chatzivasileiadis & Sabelis 1997; Agrawal et al. 2002). However, this high growth rate did not result in more rapid overexploitation (death) of the host plants, but rather, in higher population levels at the moment of overexploitation compared with T. urticae. This will result in higher numbers of mites dispersing from overexploited plants.

In conclusion, T. evansi seems to interfere with plant defences in a manner different from other herbivores. There is very limited evidence for defence suppression by herbivores (Musser et al. 2002; Bede et al. 2006; Zarate et al. 2007; Lawrence et al. 2008), and even less evidence that this suppression results in an increase in plant quality for the suppressing herbivore. Rather than merely suppressing defences downstream of the induced response, T. evansi apparently also interferes with components of house-keeping mechanisms that maintain constitutive \(WIP\) transcript levels and PI activity levels in non-damaged plants. This results in suppressed plants being better food than induced plants and herbivore-free control plants.

The last decades, much of the research on plant–herbivore interactions was focused on plant defence, but such defences are bound to trigger selection for counter-adaptations in herbivores (Karban & Agrawal 2002). The down-regulation of tomato defences by T. evansi may be an example of this. More research into the molecular mechanisms underlying plant defence suppression is needed to develop crops able to counter manipulation by herbivores. Such research will further our understanding of the evolution of plant–herbivore interactions and the interplay of plant defences with herbivore strategies to counter these defences (Karban & Agrawal 2002).

ACKNOWLEDGEMENTS

We thank Prof. G.J. de Moraes, University of São Paulo, Brazil for Phytoseius longipes, several anonymous referees for constructive comments and Ted Turlings for excellent comments and editing. RAS was supported by WOTRO (W82-281), FL and AP by CNPq, AJ by FAPEMIG (CBB-30003/09).
