ABSTRACT
In this study, age and sex compositions, length distributions, growth parameters and length-weight relationships of common sole populations were determined in Güllük Bay, southern Aegean Sea, Turkey. Trammel nets and beach seines which have different full mesh sizes were used to obtain samples. Sex ratio (female:male) was found to be 1.14:1. Growth parameters of the common sole in Güllük Bay was described as; $L_\infty=33.95$, $K=0.208$ y$^{-1}$, $t_0=-0.032$, $L_\infty=31.98$, $K=0.236$ y$^{-1}$, $t_0=-0.037$ y and $L_\infty=29.11$, $K=0.324$ y$^{-1}$, $t_0=-0.030$ y, for sexes combined, females and males, respectively. Length-weight relationships for combined sexes, females and males were $W=0.0079L^{3.064}$, $W=0.0072L^{3.101}$ and $W=0.0088L^{3.024}$, respectively. Combined individuals and females showed positive allometric growth and males showed isometric growth. Ages ranged between 0-9 years. Study results could be useful for further common sole fishery management strategies.

Keywords: Common sole, Aegean Sea, trammel net, small-scale fishery, flatfish

INTRODUCTION
Flatfishes are a highly diverse fish group. According to taxonomists, 1820 species have been identified, however, 1073 are valid and the Soleidae family includes approximately 281 species (181 valid species) (Eschmeyer & Fong, 2017). 56 of these flatfish species have commercial importance all over the world and 10 in the Mediterranean (Ulütürk, 2012). In Turkey, a few turbots, sole and flounder species are commercial (TUİK, 2016). Common sole (Solea solea) is one of the highest commercial flatfish species in Turkey (Türkmen, 2003) as in some other parts of the world (Teixeira, 2007). Therefore, it is a targeted species by fishermen in some periods.

Güllük Bay is an important fishery area for both small-scale and industrial fisheries. Beside trawling and purse-seining, small-scale fishery (especially trammel net fishery) is common in this area. Species-specific fishing gear (such as red mullet nets, shrimp nets, common dentex nets etc.) are densely used. One of these nets is the common sole trammel net and is used in certain periods in Güllük Bay. Especially, the period which is from the middle of September to the middle of February, is locally named as common sole period.

Due to having high commercial importance, the common sole stocks need proper management strategies. Therefore, there have been many studies conducted on common sole including growth (Deniel, 1990; Enberg et al., 2008), stock assessment (Mehanna & Salem, 2012), and population parameters (Türkmen, 2003).

Common sole studies are both discontinuous and insufficient in Turkey. The objective of the present study was to determine age and sex compositions, length distributions, growth parameters and length-weight relationships of the common sole population in Güllük Bay for further fishery management strategies.
MATERIALS AND METHODS

Fishing operations were conducted between October 2013 – November 2015 in Güllük Bay and Boğazıci lagoon, which are in the Southern Aegean Sea, Turkey (Figure 1).

Samplings consisted of two parts; first was just total length measurement on board due to difficulties of taking weights of the specimens by a digital laboratory scale, second was laboratory examinations for length, weight and age determinations.

Data were obtained from commercial small-scale fishermen who use 80-90 mm full mesh size trammel nets. Additionally, beach seine and 52-56-64 mm full mesh size PA trammel nets were used to obtain various length classes in the lagoon area. Sampling depths varied between 0.5m and 70m. Samples were stored in ice and were brought to the laboratory.

Total lengths were measured to the nearest 0.1 cm and weighed individually to the nearest 0.01 g. Sagittal otoliths were removed, cleaned and stored in Eppendorf tubes. Otoliths were embedded in polyester, and two thin sections (0.1 mm) were cut along a transverse plane through the focus of the otolith by a Buehler Isomet Lowspeed Saw. The ages were read under a light microscope by three independent experts. Contradictory readings were discarded from age estimations. The theoretical birthday was considered as 1 January (Froglia & Giannetti, 1985). Exact ages were calculated according to sampling month (1 month=0.083 year).

Length weight relationships were calculated according to formula $W=aL^b$ (Ricker, 1973). Where; $L$ is the total length, $W$ is the total weight, $a$ is the intercept of the regression curve and $b$ is the regression coefficient. If $b$ value is 3, <3 or >3, it means isometry, negative allometry and positive allometry, respectively. Significant difference of $b$ values from 3 were tested with the $t$-test (Pauly, 1993).

Growth performance was estimated with the phi-prime test ($\phi$) (Pauly and Munro, 1984);

$$\phi = \log K + 2 \log L_\infty.$$

RESULT AND DISCUSSION

On board measurements and laboratory examinations

In total, 2165 individuals were evaluated in the study. The total length of 1029 individuals were recorded on board. The total lengths varied between 19.1 and 42.1 cm (Figure 2). The maximum total length, 42.1 cm, was measured on board. It was not possible to determine the sexes of the individuals on board.

According to laboratory examinations, 1136 individuals were evaluated and 607 of the individuals were female and 529 individuals were male. Sex ratio was found as 1.14:1, female to male, respectively. According to the chi square test, a significant difference was found between female and male ($p<0.05, \chi^2=5.35$).

Female total lengths ranged between 7.1-31.1 cm and male total lengths ranged between 3.9-28.7 cm (Figure 3).

Total lengths and weights of 1136 individuals were evaluated to determine length and weight relations. Total lengths ranged...
from 3.9 to 31.1 cm and weights ranged from 0.24 to 458.67 g. Total lengths and weight regressions were calculated for combined sexes, females and males, separately. $b$ values of combined, female and male individuals were compared with isometric growth. While combined individuals and females showed positive allometric growth ($p>0.05$), males showed isometric growth ($p<0.05$) (Table 1).

Length-frequency distributions provide a vision (Khan & Khan, 2014) to help understand when the fishing pressure starts and ends. Length range (2.9-42.1 cm) shows us the significance of the area in terms of maintaining common sole’s generations. According to Turkish fishery communiques, the minimum landing size of common sole is 20 cm. However, an individual with only 9.1 cm total length was caught in a commercial 52 mm trammel net. Capture of small individuals by commercial nets means fishing pressure is at the beginning of the common sole lifespan. Cerim & Ateş (2016) found optimum catch sizes to be 23.20 and 27.02 cm for 80 mm and 90 mm full mesh sized trammel nets, respectively. These findings are suitable in terms of length-based fishery management. However, the 16-22 cm length range (the second most observed length range in length-frequency distribution) originated from lagoon samplings (52, 56 and 64 mm full mesh size trammel nets). According to length-frequency distributions, as a great majority of small individuals are captured in the lagoon area, Boğaziçi lagoon area could be characterized as a spawning or nursery area. Therefore, lagoon fisheries should be managed by taking into consideration this feature. On the other hand, if the fishing pressure exceeds the optimal population growth, common sole stocks may collapse in the future.

### Age determinations
The otoliths of 235 individuals were used for age determination. Fishes were chosen randomly to obtain various length classes without considering their sexes. Therefore, the number of females and males varies.

Ages were between 0-9 years. Ages distributed between 1-8 year for females (148 individuals) and 1-7 years for males (75 individuals) (Figure 4). For some fish, sex determinations were impossible due to having too small or transparent gonads and no internal organs (occasionally, internal organs are eaten by an Isopod species after the fish is entangled in the net). However, these individuals (i.e. 12 unsexed individuals) were incorporated into age determination (some of 0, 8 and 9 years old individuals belong to this unsexed group). Length related ages of combined females and males are shown in Tables 2, 3 and 4.

Length at ages are given in Table 5. Methods of the previous studies’ age determinations were similar. However, some of the total lengths which were related to their ages in other previous studies, are larger or smaller than the present study results. Firstly, the difference in size-compositions could be an effect on these variations. On the other hand, these variations could have originated due to some environmental factors such as pollution (Authman et al., 2015), fishing and temperature (Tu et al., 2018) and especially food availability (Ujjania et al., 2012; Gupta & Banerjee, 2015). Furthermore, size variation may be affected by genet-

| Sex    | n   | $a$  | $b$  | C.I. of $b$ | S.E. of $b$ | $R^2$ | Growth Type |

* Ø estimated by the present author.
ic factors (Exadactylos et al, 2013). Phi-prime values of previous studies showed no differences with the present study (p>0.05). Therefore, the growth of common sole could not be correlated with just food availability and other environmental factors could be responsible for length at age variation.

\[ L_\infty \] values are different from other studies (Table 6). This variation could emanate from different sampling gears and maximum catch lengths. Moreover, the \( L_\infty \) of combined sexes was higher than the \( L_\infty \) of males and females. This situation was due to the incorporation of unsexed individuals into the age estimation.

**Possible effects on growth**

Growth of fishes is different from other animals. After maturation, although growth slows down due to the transferring of resources to reproductive parts of body, it continues (Enberg et al., 2008). Flatfishes also have similar lifecycles to other fishes and this similarity is likely to reflect temperature, food availability and energetics (Nash & Geffen, 2015).

Growth of common sole were revealed by different observations and considerations. According to some researchers, growth of common sole does not depend on food limitation (van der Veer et al., 2001; Pihl, 1989). Exadactylos et al. (2013) mentioned a potential genetic effect on growth and size variability in cultured common sole and turbot. Nash & Geffen (2015) stated that many flatfish species show an increased growth rate within increasing exploitation levels due to a decrease in population size and an increase in food availability under these circumstances. On the other hand, during the first 2 to 3 years, juveniles are found in nurseries before migrating to deeper waters (ICES, 2012) and also food availability and temperature effects the growth on the nursery grounds (Nash & Geffen, 2015).

Growth may be affected by interspecific food competitions. Vinagre (2007) found that priority of cohort colonization of both \( S. \) senegalensis and \( S. \) solea in estuaries effects growth rate and \( S. \) senegalensis has a higher growth rate than \( S. \) solea. In early colonization, low competition and high food availability may affect the growth rate. Besides, Moliner et al. (1991) determined that diets of \( S. \) solea and \( S. \) senegalensis are very similar in the western Mediterranean and \( S. \) senegalensis is now extending its range to the west Mediterranean Sea and is thought to be competing with \( S. \) solea, at least in the north-west part of the basin (Tous et al., 2015). Similarly, \( S. \) solea may have food competition with other flatfishes (e.g. \( Microchirus \) ocellatus, \( Monochirus hispidus, Citharus liguatula, Arnoglossus spp \). etc.).

Except competitions, water pollution may be another reason that affects fish growth. Bhatnagar & Devi (2013) stated that good water quality is important for survival and growth of fish. Gülük Büyüğü sampling area is the most important aquaculture center in Turkey. Yıldız et al. (2002) conducted a study in Gülük Büyüğü about marine pollution sources and they mentioned the Sançayır river (sewage from the Milas district discharges into the Sançayır river), Gülük Harbor and marine traffic, tourism, aquaculture systems, domestic wastes and atmospheric pollutants may have a pressure on Gülük Büyüğü. Fish growth may be negatively affected by the existence of the aforementioned pollution types.

**CONCLUSION**

Monitoring of biological parameters constitutes the main data for fisheries. Therefore, fishery management should be structured on biological data to understand the status and to manage fish stocks. More studies should be conducted in different fishing areas to gain more information about wild stocks for managing commercial flatfish fisheries and aquaculture trials.

**Conflicts of interest:** The authors have no conflicts of interest to declare.

**Ethics committee approval:** This study was conducted in accordance with ethics committee procedures of animal experiments.

**Financial Disclosure:** This study was funded by Muğla Sıtkı Koçman University, Scientific research Project Office with Phd thesis project number BAP 13/119.

**Acknowledgement:** We would like to thank Boğazıcı and Gölürk büyükü sole fishermen for their valuable support and to Burak YABA and Cihan BULUT for checking grammar and spelling.
