Ultrasensitive and ultrathin phototransistors and photonic synapses using perovskite quantum dots grown from graphene lattice

Basudev Pradhan, Sonali Das, Jinxin Li, Farzana Chowdhury, Jayesh Cherusseri, Deepak Pandey, Durjoy Dev, Adithi Krishnaprasad, Elizabeth Barrios, Andrew Towers, Andre Gesquiere, Laurene Tetard, Tania Roy, Jayan Thomas

Organic-inorganic halide perovskite quantum dots (PQDs) constitute an attractive class of materials for many optoelectronic applications. However, their charge transport properties are inferior to materials like graphene. On the other hand, the charge generation efficiency of graphene is too low to be used in many optoelectronic applications. Here, we demonstrate the development of ultrathin phototransistors and photonic synapses using a graphene-PQD (G-PQD) superstructure prepared by growing PQDs directly from a graphene lattice. We show that the G-PQDs superstructure synchronizes efficient charge generation and transport on a single platform. G-PQD phototransistors exhibit excellent responsivity of $1.15 \times 10^8$ A W$^{-1}$ and specific detectivity of $4.72 \times 10^{15}$ Jones at 430 nm. Moreover, the light-assisted memory effect of these superstructures enables photonic synaptic behavior, where neuromorphic computing is demonstrated by facial recognition with the assistance of machine learning. We anticipate that the G-PQD superstructures will bolster new directions in the development of highly efficient optoelectronic devices.

INTRODUCTION

Graphene emerged as the dream material for electronic and optoelectronic applications due to its broad spectral bandwidth, excellent carrier transport properties with very high mobility (electron mobility, $>15,000 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$), and exceptional stability in ambient conditions and outstanding flexibility (1, 2). A plethora of composites and devices have been developed for applications in energy harvesting and storage, photodetectors, and transistors (3). However, a single layer of graphene absorbs only 2.3% of incident visible light (4). Moreover, to date, the responsivity of graphene photodetectors has been limited to about 10$^{-2}$ A W$^{-1}$. These limitations critically impede the use of graphene in optoelectronic and photonic devices (4). On the other hand, organic-inorganic halide perovskite quantum dots (PQDs) have risen as attractive materials for optoelectronic devices due to their bandgap tunability across the visible spectrum, high photoluminescence (PL) quantum yield, narrow emission spectrum, and high extinction coefficients (5). A major drawback is their inferior charge transport compared with graphene.

To improve the performance of graphene-based phototransistors, various approaches such as PQDs in the form of bilayers (6) or heterostructures (7) have been pursued. A phototransistor composed of a two-dimensional (2D) perovskite thin film deposited on graphene by spin coating exhibited responsivity $\sim 10^5$ A W$^{-1}$ at 530 nm (7). Pan et al. (6) has also demonstrated photoresponsivity of $1.15 \times 10^9$ A W$^{-1}$ at 520 nm using spin-coated formamidinium lead halide PQDs on a graphene layer. Presently, most of the PQD films prepared as the active layer of phototransistors by various deposition techniques have a minimum thickness of at least 100 nm. The highest photoresponsivity reported for a graphene-based phototransistor is $10^7$ A W$^{-1}$, measured with an infrared phototransistor prepared by spin coating lead sulfide (PbS) quantum dots (QDs) on chemical vapor deposition–grown graphene (8). Growing PQDs from a graphene lattice to enhance charge transfers between the two moieties constitutes an entirely new direction for electronic and optoelectronic device applications.

Here, we demonstrate that the strong photogeneration efficiency of methylammonium lead bromide PQDs can be exploited by growing PQDs from the lattice of a single-layer graphene by a defect-mediated process. The rationale for designing this hybrid superstructure stems from the ability of PQDs to absorb light and generate charge carriers. The charges generated are transferred to graphene, which transports the carriers across the active layer of the device. Through the implementation of this thin superstructure in a phototransistor geometry, we produce a photoresponsivity of $1.4 \times 10^8$ A W$^{-1}$ at 430 nm and a specific detectivity ($D^*$) of $4.72 \times 10^{15}$ Jones, which is, by far, the best responsivity and detectivity across similar devices reported to date. This is promising for the development of highly efficient optoelectronic materials for high-speed communications, sensing, ultrasensitive cameras, and high-resolution imaging and displays (9). In addition, we find the graphene-PQD (G-PQD) superstructure to behave as a photonic synapse with low energy consumption of 36.75 pJ per spike that mimics crucial characteristics of its biological equivalent, with unique optical potentiation and electrical habituation function. This is critical for pattern recognition. This enables the building of a hardware unit for the neuromorphic architecture to mimic the human brain functionalities, which is critical for applications such as pattern recognition.
RESULTS
Growing PQDs from graphene lattice
Among the techniques used to produce PQDs with very high PL quantum yield (10), ligand-assisted reprecipitation (LARP) stands out as a very versatile approach. LARP uses the mixing of polar and nonpolar solvents to synthesize PQDs at room temperature. This strategy is sufficiently mature to control the size and morphology of the PQDs (11). PQDs with a diameter below 4 nm have previously been grown, exhibiting enhanced quantum confinement (12). Following similar considerations, we initiate the growth of PQDs directly on the active sites of graphene monolayer surfaces to form the superstructure. An antisolvent toluene was added onto the precursor-coated graphene, a highly disordered spherical perovskite droplet with high concentration and large density fluctuations was formed on the graphene surface as well as in the toluene solution due to the excess of precursors (13). Next, perovskite embryos formed on the graphene sheet as well as in the toluene solution, under saturation conditions, which transformed into a stable perovskite nucleus inside the droplet beyond the critical size required for crystal formation (14). With their high Gibbs surface free energy, we find that the defects in the graphene layer provide preferential sites for the embryo formation, thereby nucleating the PQDs. It is also possible that collisions between the disordered droplet and the graphene layer led to contact nucleation (fig. S1). Electrostatic attraction with the graphene layer may also contribute to the growth via strong immobilization of the clusters formed. We find the proximity to the critical point of nucleation to decrease the Gibbs surface free energy barrier for crystallization and consequently increase the rate of nucleation. The PQDs once grown from the graphene sample were washed continuously with a nonsolvent for about 10 min to remove any PQDs, which were not grown from, but just adsorbed, on the graphene surface.

We analyze the synthesized G-PQD hybrid material by transmission electron microscopy (TEM), as shown in Fig. 1 (B to E). Figure 1B indicates that the grown PQDs were randomly distributed on the graphene layers, with a denser population along the graphene edges. We surmise that defect sites or dangling bonds on the edges favor nucleation sites for the PQDs. We find that the PQDs grown on graphene by heterogeneous nucleation have an average diameter of 3.1 nm with a size deviation of 0.5 nm (Fig. 1, B and C) for a 30-min growth process. Figure 1C reveals the spherical shape of the PQDs over the graphene surface, while Fig. 1D indicates the interplanar (d) spacing of 0.27 nm, which corresponds to the (201) lattice plane in PQDs. Fast Fourier transform (FFT) analysis (Fig. 1D, inset) confirms that the zone axis of these QDs is along the (201) direction, which is consistent with the x-ray diffraction (XRD) results (Fig. 1F). The growth of PQDs on the graphene layer is further confirmed by the TEM image in Fig. 1E, where we observe lattice distortions. We attribute these to the stress developed in the graphene lattice upon PQD crystal growth. As shown in the inset, the spectra of pristine PQDs and G-PQDs both exhibit similar major peaks at 3.3°, 4.4°, 6.5°, 9.0°, and 15.4°, corresponding to (011), (101), (201), (141), and (100) crystal planes, respectively. This confirms the crystallinity of the structures formed in G-PQDs (15). We attribute the low peak intensities observed in the case of G-PQDs to the low density of PQDs on the single-layer graphene compared with the density of the pure PQD solution drop casted for the measurements.

The binding energies in the pristine PQDs and G-PQDs were evaluated using x-ray photoelectron spectroscopy (XPS). In pristine PQDs (fig. S2), the XPS spectra mostly coincided with the signature peaks of the bulk methylammonium lead bromide perovskite (5), especially for Pd-4f and Br-3d energy states. Binding energies at 67.58 and 68.62 eV correspond to inner and surface ions, respectively (5). The ratio of intensity of the two bands suggests that Br bonds were more prevalent in the core of the QDs than at their surface. The N-1s binding energies confirm the existence of two chemical environments of the N element with bands at 398.21 and 400.86 eV, corresponding to N-C and amine (−NH₂) ions, respectively. The Pb-4f spectrum also exhibited two peaks positioned at 137.77 and 142.63 eV, corresponding to the levels of Pb-4f5/2 and Pb-4f7/2 associated with Pb⁵⁺ in PbBr₃ (16), respectively. The C-1s spectrum with peaks at 284.03 and 284.43 eV confirms the presence of C–H/C–C and C–N bonds, respectively. All core-level XPS spectra corresponding to Pb-4f, Br-3d, C-1s, and N-1s (fig. S3) exhibited an increase in binding energies in G-PQDs compared with PQDs. The C-1s spectrum of G-PQDs also revealed sp² bonding with the apparition of a peak at 284.09 eV. We note that these results indicate binding between PQDs and the graphene layers, as evident from the fact that nonbound bilayer systems consisting of CsPbBr₃/QD/graphene oxide composite (17) and organic molecule-graphene interfaces previously characterized with XPS showed no signs of change in binding energies.

We further investigate the effect of growing PQDs on the graphene sheet with Raman spectroscopy. Pristine graphene exhibited the signature of a high-quality single layer, with a band ∼1580 cm⁻¹ corresponding to the stretching of the C–C bond in the plane (Fig. 1G), which is in agreement with the change in binding energies observed with XPS. To test the attachment of PQDs on a graphene surface, we drop casted a film of prepared PQDs on graphene. The Raman spectra of graphene were not affected in this case (Fig. 1G). However, we find that in G-PQDs, the shift of a G band to a lower wavelength accompanied the apparition of a D band at ∼1340 cm⁻¹. We attribute the D band in graphene to a zone boundary mode (A1g) usually found at an armchair edge of graphene sheets. The results, thus, suggest that the growth of the PQDs created a sufficiently large density of local armchair edges in the graphene sheets to be detected by Raman spectroscopy.

Optical absorption is an important parameter for a highly sensitive photodetector. The grown G-PQD film absorbs in the visible wavelength region with a maximum of 434 nm and a secondary band maximum of 451 nm (Fig. 2A). We attribute these to two different sizes of PQDs grown on the graphene layer. The 434-nm band corresponded to the smaller PQDs. The PL spectrum exhibited peaks at 462 and 479 nm corresponding to a bandgap of 2.6 to 2.7 eV. The steady-state PL intensity decreased in G-PQD superstructures compared with pristine PQD film, which we attribute to additional charge transfer pathways provided by graphene in addition to the intrinsic radiative channels for excited-state charge transfer (17). Together, these results suggest that the G-PQD layer is a potential candidate for high-performing phototransistors detecting at blue illumination.

To further understand the photophysical properties of the material, the excited-state dynamics of the G-PQD superstructure were probed with time-correlated single photon counting (TCSPC). While the PQDs on a glass substrate exhibited a biexponential decay similar to
previously reported literature (18) with an average fluorescence decay time of 2747 ns, G-PQDs exhibited an average fluorescence decay time of 749 ns (Fig. 2B). Single-layer graphene has displayed similar quenching effects with previously reported perovskite nanoparticles and PQDs on single-layer graphene deposited by spin-coating methods (19). We believe that the longer fluorescence lifetimes observed in this study along with reported low exciton binding energy of perovskite materials could infer a photoinduced electron transfer mechanism as the predominant pathway for the quenching effects. Overall, the observed PL quenching indicates fast charge transfer in G-PQD superstructure due to high carrier mobility in graphene and the direct contact between the two components.

The growth of PQDs on graphene may facilitate charge transfer through π-π electron interactions between PQDs and the sp²-hybridized graphene layer. Previously reported density functional theory (DFT) studies confer some insights into the electronic properties of the two different termination planes in perovskite crystals (20). It is important to understand the surface termination of perovskite crystals because heterogeneous nucleation of PQDs likely initiates
Highly sensitive ultrathin phototransistors

The aforementioned characterizations imply a direct growth of PQDs on the graphene surface, which facilitates an efficient charge transfer from PQDs to graphene. The charge generation and transfer efficiency of this superstructure were evaluated in a phototransistor geometry fabricated on a silicon dioxide/silicon wafer (fig. S5A). In this configuration, graphene constitutes a carrier transport channel, and PQDs play the role of the photoabsorbing material, as shown in Fig. 3A (inset). The pristine graphene used for this experiment was hole dominated. The current-voltage (drain current $I_{DS}$ versus drain voltage $V_{DS}$) characteristics of the phototransistor in dark conditions and under 440-nm illumination with zero gate voltage are shown in Fig. 3A. These $I_{DS}$-$V_{DS}$ curves indicate an ohmic behavior both for the forward and reverse bias, without any trace of hysteresis. We observe a substantial enhancement in photocurrent with an increase in illumination intensity. The phototransistor responsivity ($R$) was calculated as the ratio of the photocurrent density $J_{ph}$ to the incident light intensity $I_{light}$

$$R = \frac{J_{ph}}{I_{light}}$$ (1)

Figure 3B represents $R$ over the 300- to 700-nm range. The photoresponsivity reaches a maximum at 430 nm, which matches with G-PQD absorbance peak, but slowly decreases in the 430- to 700-nm range. The G-PQD superstructure phototransistor shows a photoresponsivity of $1.4 \times 10^8$ A W$^{-1}$, which is among the highest reported responsivity, to the best of our knowledge. A very tight distribution of the responsivity was also obtained across several devices, and a box plot of the measured devices has been provided in the Supplementary Materials (fig. S5B). The device prepared by drop-casting PQDs on graphene showed a photoreponsivity of only $6 \times 10^6$ A W$^{-1}$. As the photocurrent generation in a single-layer graphene is very negligible when the energy of the incident photon is higher than the bandgap of PQDs, as band-to-band transition is not feasible, only electrons from the impurity levels can absorb the photons and get excited to the conduction band. This is followed by a transfer of electrons to graphene, leading to a very small photocurrent.

The schematic energy band diagram of the G-PQD superstructure is shown in Fig. 3 (C and D). The work function of a single-layer pristine graphene was around 4.56 ± 0.04 eV, whereas the Fermi level of PQD was 4 eV (27). We find that when PQDs are grown on the graphene sheet, the work function mismatch between the two materials leads to a built-in field developed at the interface of graphene and PQDs to align the Fermi levels. The Dirac point ($V_{Dirac}$), obtained from the drain-source resistance as a function of gate voltage under dark and illumination conditions, observes a drastic shift from above 80 to 70 V. We attribute this to the charge transfer from the PQDs to the graphene layer (fig. S6). Figure 3E shows the resistance as a function of back-gate voltage ($V_{BG}$) under different illumination intensities at a fixed drain-source voltage ($V_{DS}$) of 500 mV. As the light intensity increases, $V_{Dirac}$ at which the device resistance reaches its maximum value, shifts toward a higher voltage because of the photogating effect (8). Under illumination, the PQDs absorb the photon energy and generate electron-hole pairs, which are effectively dissociated at the graphene/PQD interface by the built-in field. We find that the photogenerated holes are transported to the graphene from PQDs, and the photogenerated electrons remain on the PQDs. The photogating effect, induced by the accumulated electrons in the PQDs, produces a hole current in the graphene through capacitive coupling (similar to the application of a negative voltage on graphene) and shifts $V_{Dirac}$ of the G-PQD superstructure to a higher $V_{BG}$.

Furthermore, when $V_{BG} < V_{Dirac}$, the carrier transport in the graphene channel is hole dominant, which can increase the transfer rate of photogenerated holes, leading to a higher drain-to-source current. Therefore, a positive photoresponse was observed under illumination. In contrast, when $V_{BG} > V_{Dirac}$, the electron becomes the dominant charge carrier in the graphene channel, leading to a negative photoresponse or current quenching. This is due to the recombination of transferred photogenerated holes and induced electrons by the back-gate electrode. Moreover, as the illumination intensity increases, the trapped photogenerated electrons in PQDs

$$D^* = \frac{RA^{0.5}}{2qL_d^{0.5}}$$ (2)
offer a more effective negative photogating effect by inducing more positive carriers in the graphene channel via capacitive coupling. This leads to the shift in the Dirac point toward a more positive back-gate voltage. The photoinduced shift of $V_D$ at different intensities of monochromatic light (437 nm) is shown in Fig. 3F. Moreover, this photogating effect that occurs when light intensity increases results in more accumulation of induced charge in graphene channel, hence leading to an enhancement in surface potential ($\lambda$). In this case, the photogating effect is controlled by light-induced gate voltage of the field-effect transistor (FET) structure and is very difficult to compare to the photogating effect observed in metal filament formation that can lead to pronounced resistive switching effects in QD-based photonic resistive random-access memory (30).

Figure 3G illustrates the shift of the Dirac point as a function of incident light intensity. Inset: Variation of photocurrent under different illumination powers at 437 nm.

Table 1. Performance summary of previously reported graphene-QD–based phototransistor (MA: CH$_3$NH$_3^+$, FA: NH$_2$CH = CH$^-$. MOF, metal-organic framework.

| Active materials | $R$ (A W$^{-1}$) | $D^*$ (Jones) | EQE (%) | $\lambda$ (nm) | Thickness (nm) | Reference |
|------------------|-----------------|--------------|---------|----------------|----------------|-----------|
| FAPbBr$_3$-graphene | $1.15 \times 10^5$ | $3.42 \times 10^7$ | 520 | | | (6) |

photocurrent increases as the incident photon power increases. As light intensity increases, more holes are generated and transferred to graphene, which induces a higher photogating effect and higher photocurrents. For bilayer films prepared by other deposition techniques on graphene for which there exists a thin space between the PQDs and the graphene films, the photocurrent response was much smaller than in the G-PQD device. To better understand the charge transfer effect, the photocurrent response was simulated using COMSOL. We compare two scenarios: (i) PQDs just touching the graphene surface forming a bilayer configuration and (ii) PQDs in close contact with the graphene film (i.e., considered as being inserted into the surface, grown from defect sites of graphene). The Fermi-Dirac semiconductor model was used to develop the G-PQD model, and continuous Fermi energy levels were used at the interface between the PQDs and the graphene films. To simplify the simulation, a 40 nm–by–40 nm area of the graphene film (film thickness, 0.3 nm) was used for all devices, and a total of 15 PQDs were attached randomly on the graphene film to form the G-PQD devices. The photocurrent effect was also simulated with two different PQD sizes (3 and 5 nm) in the G-PQD superstructure. A voltage of 1.5 μV was applied at the two ends of the film, and an incident plane wave with a wavelength of 430 nm was considered, as represented in Fig. 4 (A and B), respectively. We obtain a photocurrent response close to zero from simulations for graphene films, even at different light intensities. For G-PQD layers, the photocurrent is 0.3 pA under 150-nW illumination and 1.5-μV applied field. Among all devices, the photocurrent responses of G-PQD devices are the largest, which indicates that the charge transfer from the grown PQDs to the graphene film is much larger than that for PQDs deposited on the graphene film. This shows that growing PQDs on graphene provides a direct conduction path for charge transfer, which agrees with our experimental results.

Next, we investigated the transient response of the G-PQD superstructure. The transient photoresponse of the G-PQD superstructure under periodic white light illumination (33 mW cm−2) with on and off time of 20 s was investigated, as shown in Fig. 4C. The results reveal a relatively fast and stable reproducible photocurrent response. A quick rise of photocurrent as soon as the light is turned on was followed by a drop back to initial values when light was turned off. This indicates that the device can act as a light-activated switch. The response time for the photocurrent to rise up to 80% was about 0.45 s (Fig. 4D), which is comparable to the reported values in a graphene-perovskite structure (31). The photocurrent decay time was about 0.85 s for 50% decay from the maximum value. The longer response time was due to more complex factors, predominantly from the quantum capacitance of graphene and the time for relaxation charge transfer along ligands (32). Using this response time measurement, the photoconductive gain (G) can be calculated on the basis of the equation

\[ G = \frac{\tau_{\text{lifetime}}}{\tau_{\text{transit}}} = \frac{\tau_{\text{lifetime}}}{\tau_{\text{transit}}} \frac{V}{I^2} \]  

(3)

where \( \tau_{\text{lifetime}} \) is the lifetime of the photogenerated carriers and \( \tau_{\text{transit}} \) is the duration of the carrier transport within the channel. This was calculated using transistor mobility (\( \mu \)) and applied drain-to-source voltage (V) of 0.5 V and a fixed channel length (l) of 15 μm. The calculated field-effect mobility of pristine single-layer graphene and the G-PQD superstructure are 2786 and 2580 cm2 V−1 s−1, respectively. Therefore, the photoconductive gain of the G-PQD superstructure varies between 1.8 × 108 and 1 × 109 for lifetimes of 0.29 and 1.84 s, respectively. These values are very similar to the ones reported by Konstantatos et al. (8) in hybrid graphene-PhS QD phototransistor. The photoconductive gain can be further improved by increasing the carrier mobility of PQDs and introducing shorter chain ligands. We can attribute the high photoconductive gain and responsivity to the high charge carrier mobility of graphene as well as the direct charge transfer pathway between the PQDs and the graphene layers.

**Neuromorphic photonic synapses and facial recognition**

We observe a fast and stable photodetection property of the G-PQD superstructure when the gate voltage is maintained constant at 0 V. Tuning the gate voltage toward a positive direction can, however, limit the recombination of photogenerated carriers. Under light illumination, the gate-tunable device can therefore achieve a higher conductance state, which is retained even in the absence of light. This type of synaptic behavior, which is facilitated by gate tunability, is of great importance for neuromorphic computing.

In traditional von Neumann architecture, huge time and power spent in transporting data between memory and processor inevitably impose limitations in the performance and scalability of the structure, popularly known as the “von Neumann bottleneck” (33). This major drawback leads to severe problems in data centric applications, such as real-time image recognition, data classification, and natural language processing. Neuromorphic computing has emerged as a superior platform for parallel energy-efficient data processing with high accuracy and storage of information, which outperforms the von Neumann architecture (33). Figure 5A shows the anatomy of two biological neurons connected via a biological synapse. A synapse (Fig. 5B) acts as a channel of communication between two neurons. Information broadcasted from one neuron acting as presynaptic cell (transmitting neuron) is conveyed to the other acting as postsynaptic cell (receiving neuron) through a synapse. The synaptic behavior can be strengthened (potentiated) or weakened (depressed) using appropriate triggers of optical pulses. Measurements of synaptic plasticity, including short-term plasticity (STP), long-term plasticity (LTP), and long-term depression (LTD), are emulated to resemble the synaptic behavior of its biological counterpart. Here, we show that the G-PQD superstructure acts as an artificial photonic synapse, where the presynaptic signal is the external light stimuli in the form of optical pulses and the postsynaptic signal is the current obtained across the G-PQD channel keeping both drain source and gate voltage fixed (29).

To understand the synaptic dynamics of the device under different conditions of the presynaptic signal spikes, we recorded the change in conductance for light (specific wavelength of 440 nm) that has different intensities varying from 190 nW cm−2 to 1.1 μW cm−2 (Fig. 5C). Conductance of the device changes under the application of light when voltage biases were applied to the gate (10 V)/drain (0.5 V) electrodes of the device, while the source electrode was kept grounded. We achieve a higher level of conductance for light of highest intensity (1.1 μW cm−2) as compared with the other intensities. At high intensity, we attribute enhancement in the conductance state to the formation of more photogenerated carriers. The effect of paired pulse facilitation (PPF), a special case of STP due to two closely spaced light pulses, is shown in Fig. 5D (see details in figs. S7 and S8). The PPF index increases when the photogenerated carriers from the first light spike, before recombination, are appended with those originating from the second light spike, resulting in an increase in the device conductance. The PPF ratio fades with the increasing
photonic pulse intervals. A high value of PPF suggests the low rate of decay of the synaptic response, whereas a low value marks a high rate of decay. Therefore, it is seen that the index exponentially decreases with increasing off time between two pulses (delay between two pulses). This is indicative of the fact that reduction in off time between two pulses (≤10 s) amplifies the postsynaptic response, leading to STP. Therefore, when the device is triggered with repetitive training pulses, the learning effect in our device can be enhanced. In a training scheme where repetitive pulses (having off time of ~5 s) are used, the weight of the photonic synapse is governed by the number of pulses. Normalized conductance of the device for a varying number of pulses at a fixed wavelength of 440 nm with an intensity of 1.1 μW cm⁻² is shown in Fig. 5E (see details in fig. S9). The normalized conductance attains a value of ~1.11 for one pulse and gradually increases as the number of pulses increases. The effect of (i) number of pulses and (ii) delay between the pulses on the device conductance is exponential in both cases, except for the number of pulses causing an exponential rise and the delay causing an exponential decay. It becomes essential to correlate the optimized off time between consecutive pulses (5 s in this case) along with the number of pulses (20 pulses in this case) to maximize conductance state. Figure 5F shows the variation in normalized conductance triggered by 20 presynaptic light spikes under a gate bias of 10 V. A change in conductance was obtained under application of light pulses and did not relax to its initial stage even when the light is switched off. LTP was induced in the device, which was sustained for 3000 s. LTP obtained by applying photonic pulses followed by LTD obtained by applying electrical pulses at drain is demonstrated in Fig. 5G. This shows the nonvolatile synaptic plasticity of our device. We find that negative pulses at drain help in depressing the potentiated device by detrapping the photogenerated carriers in the PQDs. The synaptic device shows paired pulse depression (PPD) of 99.03%, which is the percentage change in conductance of the second spike with respect to the first spike due to the application of the electrical pulses. PPD is observed when the first postsynaptic current (or postsynaptic conductance) is large, followed by a spike whose amplitude is less than the first and implies the inhibitory signal transmission. This contrasts with PPF, which is observed when the first postsynaptic current (or postsynaptic conductance) is small, and the second is larger than the first, which is based on excitatory signal transmission. We also observe gate-dependent LTP in Fig. 5H by increasing the gate bias. We find that both enhancement in conductance due to photogenerated carriers under illumination and capability of retention after removal of light increase as the gate becomes more positive. When gate voltage moves in the positive regime, electrons get trapped in the trap centers in graphene. These trapped charges lead to quasi p-doping of graphene. The higher the gate voltage, the larger the quasi p-doping of graphene. Under illumination, photogenerated holes are injected into the graphene from the PQDs, which contribute to the gain of photocurrent (or conductance) as holes are injected in a p-doped channel. This explains the jump in the conductance from the initial point to the final point, and this effect is emphasized when gate becomes more positive (holes being injected in the p⁺ channel). Moreover, the photogenerated holes injected into graphene cannot recombine with the electrons as the electrons are trapped even when the light is switched off because of positive gate voltage. The holes continue to flow in the system under the effect of drain voltage and maintain retention over a long time, resulting in LTP of the device. The energy consumption per synaptic event of optically stimulated synaptic devices is calculated using (34)

\[ dE = S \times P \times dt \]
where $S$ is the area of the device and $P$ is the power density of the input light at a spike duration of $t$. The calculation for our devices indicates that the energy consumption per synaptic event for potentiation is 36.75 pJ for the optimized spike duration of 5 s. We have also calculated energy consumption per synaptic event for devices showing photonic synaptic behavior reported in the literature and have compared them with the value obtained for our device (table S1). Our G-PQD synaptic device showed lower energy consumption with respect to the energy consumption calculated using the data of other similar devices given in the literature, as shown in table S1.

With the integrated optical information detection, processing, and retention capabilities of the G-PQD synaptic devices, they become a
potential candidate for human visual memory and in fields of pattern recognition. For real pattern recognition application, a dark current was chosen as a baseline. The fitted conductance curve of the device is shown in fig. S12, and the fitting parameters are shown in table S2. Those fitting parameters are important because they represent how a synaptic weight changes inside of the neuron network when training the network. For our optical synapses, both optical and electrical spikes were used to change the conductance. Using the fitted conductance properties of our device (35), we construct a spiking neural network to perform unsupervised machine learning and face recognition using Python. The simulation details are discussed in the Supplementary Materials. Portraits from four persons were used to train our neural network, and different portraits were used for testing. The network structure is shown in Fig. 5I. Each presynaptic neuron senses each pixel of the input images and transforms them into presynaptic spikes. After our synaptic devices, the postsynaptic signals were summed at the postsynaptic neuron, which could make it spike. Figure 5J displays the real images used for training and the synaptic weights of some corresponding output neurons, which shows the pattern recognition ability of this unsupervised spiking neural network with our device properties. By comparing the upper images (real images used for training) and the bottom images (synaptic weights of the corresponding output neurons), we find that our synapses catch the features from the portraits and realize facial recognition very well. In addition, to further detect the learning ability of our photonic synapses, 1000 figures from the MNIST (Modified National Institute of Standards and Technology) dataset were chosen for training, and 1000 different figures from the same dataset were chosen for testing, of which the results are shown in the Supplementary Materials. For real applications, if more output neurons are adapted and longer training time is used, higher recognition rates could be achieved.

DISCUSSION
In this study, we develop extremely thin superstructures by growing PQDs from graphene lattice by a defect-mediated crystal growth technique. We find that a highly enhanced charge transfer can be obtained because of the overlap of the π-electron clouds of PQDs and graphenes. The devices evaluated with the G-PQD superstructure exhibit high performances for phototransistor and photonic synapses. The phototransistors exhibit superior responsibility and specific detectivity to any other devices reported to date. The behavior is further validated by COMSOL simulations. Our approach can extend to other 2D materials, including transition metal dichalcogenides and other heterostructures, which opens the door to a new class of high-performing superstructure materials for many electronic and optoelectronic applications. The unique configuration of the PQD-graphene superstructure, which shows photonic synaptic behavior, is highly beneficial for facial recognition and future neuromorphic computing.

METHODS
Materials
Lead bromide (PbBr₂; 99.99%) and methylammonium bromide (CH₃NH₃Br; 99.5%), N,N-dimethylformamide (DMF; 99.9%), toluene (99.5%), butylamine, and oleic acid were purchased from Sigma-Aldrich and Ossila Ltd. All the chemicals were used without further purification.

Precursor preparation
Methylammonium lead bromide (CH₃NH₃PbBr) quantum dots (PQDs) were prepared by the LARP method (5). The precursor preparation involved solubilizing the precise ratio of PbBr₂ (0.2 mmol) and CH₃NH₃Br (0.16 mmol) salts in 5 ml of DMF. This was followed by the addition of 50 μl of butylamine and 500 μl of oleic acid to the perovskite solution, which was ultrasonicated for 10 min.

Device fabrication
Bottom-gated FET structures were fabricated on a 300-nm-thick thermally grown SiO₂ dielectric on p⁺ silicon. Single-layer graphene on copper foil purchased from Grolltex Inc. was wet transferred to an SiO₂ substrate as per the reported method (36). The graphene channel was patterned using photolithography and etched in oxygen plasma. Drain/source electrodes were patterned using photolithography, and 50-nm nickel was deposited using an electron beam evaporation process. The optical image of a representative graphene FET on an SiO₂/Si substrate is displayed in fig. S6. This fabricated graphene channel was dipped into a graphene precursor solution, and after 30 min, toluene was injected slowly into the solution, and PQDs were allowed to grow on the graphene channel for 1 hour. This was followed by thoroughly washing the sample to remove the excess precursor and PQDs and drying the samples by blowing N₂ gas.

Characterization
The topography of the PQD was characterized by TEM (FEI Tecnai F30 TEM) and a JEOL JEM 3010 instrument. The structures of the PQDs and G-PQDs were determined using XRD analysis (PANalytical Empyrean with 1.8-kW copper x-ray tube) and ultraviolet-visible (UV-vis) absorption spectroscopy (UV-vis spectrophotometer, Agilent Cary 300). The PL spectra of the films were recorded using fluorescence spectroscopy (fluorescence spectrometer, Horiba Nanolog FL3-11). The chemical bonding states of the materials were examined in detail by XPS (Physical Electronics 5400 Electron Spectroscopy for Chemical Analysis). The high-resolution XPS spectra corresponding to C-1s, N-1s, and I-3d doublets (3d₅/₂ and 3d₇/₂) and Pb-4f doublets (4f₅/₂ and 4f₇/₂) were analyzed using an XPS Peak version 4.1 program. Raman spectroscopy was performed on a WITec 300RA confocal Raman system with excitation laser at 532 nm and a 100× objective. Atomic force microscopy (AFM) measurements were carried out on a multimode system in contact mode. All phototransistor characteristics were measured in a probe station using a Keysight B1500A Semiconductor Device Analyzer under illumination from a halogen lamp fitted with a Newport monochromator. Light intensity was measured by a Newport power meter through calibrated Si photodiode. All photodetector measurements were conducted in ambient temperature.

Time-correlated single photon counting
TCSPC curves were collected while exciting the samples with a PicoQuant LDH-P-C-375 pulsed laser driven by a PDL 800-D controller. The repetition rate was set at 5 MHz. Laser intensity was adjusted to keep the photon emission rate below 5% of the laser repetition rate. Photons were collected on a single photon counting detector (PicoQuant, Micro Photon Devices, PDM series) connected to a PicoHarp 300 TCSPC module that detects the photon arrival time. The laser excitation was filtered with a 375-nm interference filter, while the emission was filtered by a 400-nm long pass emission filter.
filter. TCSPC decay curves were fitted with FluoFit software (FluoFit Pro 2009, 4.4.0.1, PicoQuant). Because TCSPC decays were collected locally on G-PQD superstructures using a custom-built microscope, an instrument response function was not obtained, and decay curve fitting was accomplished via a tail fitting process.

Simulation
For COMSOL simulation (version 5.4), Semiconductor module, Wave Optics module, and Semiconductor-Electromagnetic Waves Coupling were used. Wave Optics were used to simulate the light absorption of the materials, in which a plane wave was incident on the film and the full field was calculated. Under light illumination, PQDs and graphene film domains were calculated by the Semiconductor module to get the photocurrent response, in which Fermi–Dirac carrier statistics were used.
