Abstract
The paper reports the adsorption studies of asphaltenes of Iran’s heavy crude oil on some natural and synthetic aluminosilicates. Asphaltenes were precipitated using n-heptane. Toluene was used as a precipitating solvent of asphaltenes and several zeolites including 4A, ZSM-5, Clinoptilolite, and La-modified bentonite (Phoslock) as adsorbents. FTIR analysis indicated the asphaltenes which comprise a complex of aromatic, aliphatic, and polar compounds. The pore size and outer surface area of the adsorbents were determined by BET method and the following order was found between outer surface areas: ZSM-5 (238.27 m² g⁻¹) > Clinoptilolite (28.75 m² g⁻¹) > Phoslocks (27.92 m² g⁻¹) > zeolite 4A (21.11 m² g⁻¹) > Zeolite 13X (317.24 m² g⁻¹). Besides, the adsorption isotherms were investigated with the conventional isotherm models and it was indicated that the Langmuir isotherm fitted the experimental data. Zeolite 13X with the highest specific surface area and pore size exhibited the maximum adsorption capacity, indicating that there is a direct relationship between surface area and adsorption capacity. However, it seems that the pore size effect is more prominent because of the large size of asphaltene’s molecules.

Introduction
The precipitation of asphaltenes in oil and its negative impact on the petroleum industry is an important problem in practice [1]. The increase of asphaltenes content in crude oil increases the tendency to precipitate.

Asphaltenes are soluble in aromatic solvents but insoluble alkanes. They are polar, surface-active and densest [2]. The asphaltenes are comprised of polyaromatic cores adhered to aliphatic chains. The aliphatic chains usually include heteroatoms such as sulfur, oxygen, nitrogen, and some transition metals. Nickel, iron, and vanadium are the most common metals found in asphaltenes [4, 25]. There are multifunctional groups in asphaltenes and they have high molecular weight. Determination of molecular weight of asphaltenes by different physical methods in various solvents concluded that asphaltenes are associated and form aggregates [22].

The adsorption of asphaltenes is studied to prevent productivity losses of petroleum reservoirs.

Adsorption studies are investigated by asphaltene precipitation and then resolubilize in a solvent. According to the concentration of asphaltenes, morphology and nature of the adsorbent and adsorbed asphaltenes and nature of the adsorbents different mechanisms have been developed and multilayer and monolayer adsorptions were reported [8, 9]. Some researchers reported that the adsorption of asphaltene on mineral adsorbents mostly followed the Langmuir adsorption model [10].

Dubey and Waxman [7] studied the adsorption experiments in different solvents and on some mineral surfaces. The type I and II isotherms of Langmuir were followed by them [8, 9]. Nassar [19] studied the adsorption of asphaltenes onto alumina nanoparticles in 2010. The results agreed well with the Langmuir isotherm model. Nassar et al. [18, 20] studied the oxidation of asphaltenes and adsorption onto six different nanometal oxides. The Langmuir model was well fitted for all the six nanoparticles. In 2012, they were used from iron oxide nanoparticles for rapid adsorption.
and enhanced catalytic oxidation of thermally cracked asphaltenes. The results fit well to the Langmuir model. Franco and Nassar [8] chose 12 types of nanoparticles and investigated their chemical effect on asphaltenes adsorption in 2013, which the results were fitted to both the Freundlich and Langmuir models.

Different inorganic materials could be used for asphaltene adsorption. Phoslock is a type of the modified bentonite in that some Na⁺ are replaced by La³⁺ [11].

Zeolites are called as magic materials. They have a three-dimensional crystalline structure and are considered as a type of aluminosilicates. They are comprised of units of AlO₄ and SiO₄ tetrahedral, arranged to result in an open structure. Some zeolites are naturally found in the environment and many of them are synthesized. The zeolites of A, X, and ZSM-5 are of three types of synthetic zeolites [14]. A-type zeolites have different pore sizes, which the most common sizes are 3, 4 and 5 Å. A-type zeolites are usually synthesized in alkali media. In the synthesis of zeolite 4A, the ratio of SiO₂/Al₂O₃ varies between 1.92 and 2.08 to give a pore opening of 0.38 nm [21]. The pore size of zeolite X is 0.74 nm instead of 0.38 nm in zeolite A. The ratio of SiO₂/Al₂O₃ in zeolite X is between 2.0 and 3.0. The SiO₂/Al₂O₃ ratio of ZSM-5 varies in a wide range and range of pore size is 0.54–0.56 nm [3].

This study aimed to study the adsorption isotherms of asphaltenes over some mineral absorbents (natural and synthetic zeolites and Phoslock). The relationship between structure and sorption is investigated. The asphaltenes were precipitated from Iran crude oil. The structure of the asphaltenes is investigated by FTIR and the specific surface area of the adsorbent was studied by BET surface area.

**Materials and methods**

**Materials**

Asphaltenes in Iranian crude oil were precipitated. The general property analysis of crude oil is as Table 1. The heavy oil studied in this work is from a reservoir located in the South of Iran.

| Table 1 | General properties of Iran crude oil |
|---------|-------------------------------------|
| Characteristics | Result |
| Specific gravity (15.6 °C) | 0.8801 |
| API gravity (°API) | 29.3 |
| Asphaltene content (wt. %) | 3.5 |

**Methods**

**Precipitation of asphaltenes of crude oil**

Asphaltenes of the crude oil were precipitated using a standardized procedure [4]. N-heptane and crude oil were mixed at a volume ratio of 20/1. At ambient temperature, the mixture was sonicated for 2 h. Then, it was stirred at 300 rpm for 22 h. The precipitated fraction was filtered using a 0.45 μm membrane filter. Suspension of asphaltenes in heptane was centrifuged at 5000 rpm for 15 min and left to rest for a day. The sample was washed with n-heptane to reach a shiny black color for asphaltenes. Then, the sample was dried at 25 °C for 12 h. It was dissolved in toluene for preparing solutions from 50 to 1500 ppm [14].

**Adsorbent characterization**

The pore size and BET-specific surface area of the adsorbent were determined using the N₂ adsorption/desorption isotherms at −196 °C, using an NOVA 2000. The FTIR spectra of the sample were recorded in transmittance using a Bruker spectrometer (model TENSOR 27) in the range 400–4000 cm⁻¹. The X-ray diffraction (XRD) pattern of adsorbents was recorded at 2θ = 5–70° by a Philips PW1800 diffractometer and Cu Kα radiation (λ = 1.54 Å).

**Adsorption experiments**

The calibration curve of absorbance versus asphaltenes concentration at 400 nm was constructed from the prepared solutions with the known concentrations [1, 4, 15, 17]. A linear relationship was between adsorption and concentration up to 120 mg L⁻¹. Toluene was used for dilution and a blank. In each test, 0.25 mg of the adsorbent was added to asphaltenes solutions of constant volume (10 mL) and stirred at 700 rpm for 4 h at 25 °C to reach the sorption equilibrium [14].

**Results and discussion**

The XRD patterns of the adsorbents are shown in Fig. 1. Generally, the characteristic peaks of zeolites appeared at 2θ around 5–10 and 20–27 degrees. In the XRD pattern of zeolite 4A, the sharp peaks at 2θ of 7, 9, 23, 26, 29, and 32 reveal the structure of A zeolite. All zeolite NaA samples were identified as a single-phase zeolite NaA (JCPDS card 430142) [13]. The presence of characteristic peaks of ZSM-5 zeolite at the XRD pattern of the sample indicated the ZSM-5 structure [24]. The appearance of characteristic
peaks at 2θ around 7, 10, 12, 16, 20, 23, 27, and 32 approved the zeolite 13X [12]. Phoslock which is La-modified bentonite exhibited the main peak at 2θ of 5.8 which is in agreement with the literature [5]. Finally, the peaks at 2θ of 11, 15, 20, 26, 31, 33, 35, and 38 approved the clinoptilolite zeolite [16].

By FTIR, spectrum is shown in Fig. 2, the structure and functional groups of the asphaltenes studied. According to this figure, asphaltenes show signals that correspond to the aliphatic and aromatic structure. The aromatic, aliphatic, and polar functional groups were characterized in asphaltenes. The bands at 750, 813, and 861 cm\(^{-1}\) corresponded to the out-of-plane CH bending in 1,2-disubstituted aromatic, 1,4-substituted aromatic, and 1,3-disubstituted aromatic, respectively. The band at 3452 cm\(^{-1}\) corresponds to the OH tension band and NH. The C=C aromatic bond appears at 1596 cm\(^{-1}\) and heteroatom vibration frequency such as sulfur and nitrogen is displayed between 1080 and 1030 cm\(^{-1}\). For the aliphatic characteristic, CH-stretching vibrations of CH\(_2\) and CH\(_3\) were assigned at 2920 and 2858 cm\(^{-1}\), while the peaks at 1449 and 1371 cm\(^{-1}\) represented the CH-bending vibration of CH\(_2\) and CH\(_3\) [6, 23, 26].

The specific surface area and pore size of the adsorbent are presented in Table 2. From the specific surface area and adsorption capacity of the adsorbent, we could not find any direct relationship between them.

**Equilibrium studies and adsorption isotherms**

In the isotherm study of asphaltene adsorption on the adsorbents, two types of common isotherms, i.e., Langmuir and Freundlich isotherm models, were considered and the experimental data were fitted. The isotherm equations of Langmuir and Freundlich were presented in Eqs. 1 and 2, respectively:

\[ q_e = K_F C_e^{1/n} \]

\[ q_e = \frac{q_m K_L C_e}{1 + K_L C_e} \]

where \(q_e\) is the amount of adsorbed asphaltenes (mg/g), \(C_e\) is the equilibrium concentration of asphaltenes (mg/L), \(K_F\), Freundlich constant, is roughly an indicator of the adsorption capacity [(mg/g)/(L/mg)]\(^{1/n}\), and \(1/n\) is the adsorption intensity factor (no unit) [14]. \(K_L\) is the Langmuir equilibrium adsorption constant and is related to the affinity of binding sites (L/mg). The \(q_m\) is the maximum amount of adsorbed asphaltenes per unit surface area of nano absorbents for complete monolayer coverage (mg/g) [18].

Figure 3 shows the experimental data for the rate of adsorption of the asphaltenes on different absorbents.

According to this figure, the following order results for the rate of adsorption of the asphaltenes on different absorbents:

Zeolite 13X > ZSM-5 > Clinoptilolite > Phoslocks > zeolite 4A.

Zeolite 4A due to having the small pores size has attracted very low asphaltenes. That’s why, this type of zeolites was excluded to remove asphaltenes of crude oil. Zeolite 13X due to having a relatively larger pore size and
specific surface area (according to Table 2) exhibit the highest amount of asphaltenes adsorption (Fig. 3). The zeolite ZSM-5 adsorbs the asphaltenes close virtually based on $q_m$. In higher concentrations, the adsorption rate of asphaltenes onto zeolite ZSM-5 is high. According to Table 2, the pore size and specific surface area of ZSM-5 are relatively

Table 2  Specific surface area of the adsorbents

| Adsorbent name | $S_{BET}$ (m$^2$/g) | Pore size (nm) |
|----------------|---------------------|---------------|
| Zeolite 4A     | 21.11               | 0.4           |
| Clinoptilolite | 28.75               | 0.4–0.6       |
| Phoslocks      | 27.92               | 0.48          |
| ZSM-5          | 238.27              | 0.53–0.59     |
| Zeolite 13X    | 317.24              | 1.05          |

Fig. 2  FTIR spectrum of asphaltene

Fig. 3  Experimental data for adsorption of asphaltenes onto different surfaces of nanoparticle at 298 K. Adsorbent dose, 25 g/L; shaking rate, 700 rpm, and 4 h

Fig. 4  Adsorption isotherm of asphaltenes onto the adsorbent under following conditions: $T = 298$ K, adsorbent dose = 25 g/L, agitation speed = 700 rpm, and time = 4 h. The symbols are experimental data, and the solid lines are from the Langmuir model
high, and the higher adsorption rate is attributed to the large pore size of ZSM-5. Generally, clinoptilolite, 4A, and Phoslock due to having small pore size could not adsorb large asphaltene molecules considerably and exhibit the minimum adsorption rate. Furthermore, for the first time, the adsorptive performance of Phoslock was evaluated to remove asphaltenes of crude oil.

At low concentrations of asphaltenes (<500 ppm), the rate of adsorption of asphaltenes on phoslock is more than that on ZSM-5, whereas at higher asphaltene concentration (>500 ppm), the adsorption on the ZSM-5 is more than that on Phoslock. It is concluded that at high concentration of asphaltenes, the pore size directly affects the adsorption capacity of the adsorbent.

Experimental data obtained from experiments were studied with two Langmuir isotherm and Freundlich. Figure 4 shows the results of experimental data fitted with Langmuir isotherm. Figure 5 shows the results obtained from experimental data and fitted with Freundlich isotherm.

The corresponding isotherm parameters and determination coefficient ($R^2$) for the different adsorbents are presented in Table 3. By considering the Figs. 4 and 5 and Table 3, it is observed that the experimental data are in a good agreement with Langmuir isotherm.

The maximum adsorption capacity of Zeolite 13X, ZSM-5, Clinoptilolite, and Phoslock resulted at equilibrium concentration below 500, 440, 400, and 380 mg/L, respectively, as illustrated in Fig. 4. It means that most of the equilibrium solution concentrations were relatively high. The result of $C_e$ data indicated that the Langmuir equation was best, rather than the prediction of $q_e$, below the equilibrium value, even though the $R^2$ values are high.

### Conclusions

The asphaltene content of crude oil was successfully precipitated from Iran crude oil, and its sorption was studied on four adsorbents including three zeolites and the modified bentonite (Phoslock). The experimental data were fitted with sorption isotherms of Freundlich and Langmuir models. The experimental data for the adsorption of asphaltenes were well fitted with Langmuir isotherm. The equilibrium studies for the asphaltene uptake by the adsorbents showed that the zeolite 13X has the highest adsorption capacity for asphaltene sorption and a direct relationship between the sorption capacity and specific surface area and pore size of the adsorbents resulted. According to the large size of asphaltene molecules, the pore size of adsorption is a prominent factor on asphaltene adsorption. However, more detailed studies are needed to find more effective parameters on asphaltene adsorption.
