(Received 3 September 2015; revised manuscript received 7 October 2015; published 20 November 2015)

The transition from weakly damped coherent motion to localization in the context of the spin-boson model has been the subject of numerous studies with distinct behavior depending on the form of the phonon-bath spectral density, $J(\omega) \propto \omega^s$. Sub-Ohmic ($s < 1$) and Ohmic ($s = 1$) spectral densities show a clear localization transition at zero temperature and zero bias, while for super-Ohmic ($s > 1$) spectral densities this transition disappears.

In this paper, we consider the influence of the phonon-bath spectral density on the nonequilibrium dynamics of a quantum dot with electron-phonon interactions described by the extended Holstein model. Using the reduced density matrix formalism combined with the multilayer multireference time-dependent Hartree approach, we investigate the dynamic response, the time scales for relaxation, as well as the existence of multiple long-lived solutions as the system-bath coupling changes from the sub- to the super-Ohmic cases. Bistability is shown to diminish for increasing powers of $s$ similar to the spin-boson case. However, the physical mechanism and the dependence on the model parameters such as the typical bath frequency $\omega_0$ and the polaron shift $\lambda$ are rather distinct.

I. INTRODUCTION

Quantum dissipation is an omnipresent phenomenon in diverse physical systems, ranging from quantum information [1] and quantum optics [2] to charge transfer and impurity relaxation [3,4], superconducting junctions [5], and more, spanning diverse energy, length, and time scales. Describing the effects of the environment on the dynamic response of a subsystem requires both the development of theoretical and computational tools as well as the development of simplified models necessary to account for the rich system-bath dynamics and thermodynamic phase behavior. The minimal model required to capture the essential physics of quantum dissipation involves a two-level system coupled to a bosonic bath. Perhaps the most studied version is the well-known spin-boson model [6], where it is assumed that the two-level system is linearly coupled to a harmonic bath. The effects of the environment are characterized by the properties of the bath spectral density, assumed to have a power-law dependence at low frequencies, $\omega^s (s \in \mathbb{R}_+)$, with a cutoff at higher frequencies determined by a characteristic frequency $\omega_c$. The value of “$s$” classifies the nature of the dissipative environment, often referred to as sub-Ohmic for $0 < s < 1$, Ohmic for $s = 1$, and super-Ohmic for $s > 1$.

The dynamics, equilibrium, and phase behavior of the two-level system is governed, amongst other factors, by the value of “$s$.” A notable transition from coherent to incoherent dynamics in the spin-boson model is observed as the Kondo parameter $\eta$ (dimensionless strength of the system-bath coupling) is increased or when the bath spectral density changes from super-Ohmic to sub-Ohmic [4,7,8]. This is followed by a localization transition at high values of $\eta$ in the limit $\omega_c \rightarrow \infty$ and low temperature $T \rightarrow 0$ for the sub-Ohmic and Ohmic cases. Such a transition disappears for $[4,6,9–12]$ $s > 1$. This rich behavior has been investigated by a variety of theoretical approaches including analytical [13–16] and approximate numerical techniques (for an overview, see Refs. [4] and [6]) as well as numerically exact methods such as numerical renormalization group (NRG) techniques [11,17–19], the multiconfiguration time-dependent Hartree (MCTDH) approach and its multilayer (ML) extension ML-MCTDH [20–22], and path-integral methods [4,23–26].

The dynamics and steady-state properties of dissipative quantum systems driven away from equilibrium have been the center of more recent studies, e.g., for driven spin-boson-type systems [27], or in the context of inelastic tunneling in quantum point contacts and molecular junctions [4,28–37]. The canonical model in the latter field is given by the extended Holstein model [38], in which a bridge level (occupied or empty, hence two levels) is coupled to a bosonic bath, describing the phonons, and in addition to two fermionic reservoirs representing the left and right leads. The latter are held at different chemical potentials and thus provide the source to drive the system away from equilibrium. Most studies focused on steady-state properties utilizing a variety of techniques to describe, e.g., Franck-Condon blockade [39–43], negative differential resistance [44–48], or the existence of multiple long-lived solutions, i.e., bistability [49–57]. In addition, novel numerically exact techniques uncovered interesting transient behavior [56,58–61]. A promising approach in this regard is the combination of the reduced density matrix approach [62,63] and the multilayer multiconfiguration time-dependent Hartree method in second quantized representation (ML-MCTDH-SQR) [59], used to explore the timescales and the dynamic “phase diagram” associated with the bistability [57,59,64,65].
The most striking result reported by Wilner et al. [64] for the extended Holstein model with an Ohmic spectral density is that the bistability persists on timescales exceeding the phonon-assisted tunneling time along the adiabatic potential.

At first glance, the localization transition in the spin-boson model and the bistability in the nonequilibrium extended Holstein model may result from similar physics. However, these phenomena are quite different in nature and origin. First, localization in the spin-boson model is a quantum phase transition strictly at $T = 0$, while bistability is a transient phenomenon persisting over a range of source-drain bias voltages. Second, the former vanishes in the adiabatic limit, while bistability in the extended Holstein model spans a wide range of asymmetries.

In this paper, we explore the dependence of bistability on the nature of the phonon spectral density using the combined ML-MCTDH-SQR and reduced density matrix approach. We consider a generic model Hamiltonian and the bistability in the nonequilibrium extended Holstein model with an Ohmic spectral density. Specifically, as $s$ is increased above 1 the localization diminishes. This transition, however, is not as sharp as the localization transition.

II. MODEL HAMILTONIAN AND SPECTRAL DENSITIES

To describe the effect of different forms of dissipation on nonequilibrium transport in a quantum system with electron-phonon interaction, we consider a generic model Hamiltonian describing, e.g., a quantum dot or a molecular junction:

$$H = H_S + H_B + V_{SB}. \tag{1}$$

Here, $H_S = \varepsilon_d d^\dagger d$ is the system Hamiltonian representing the electronic degrees of freedom of the quantum dot with creation/annihilation fermionic operators $d^\dagger d$ and energy $\varepsilon_d$. For simplicity, we assume that the quantum dot is represented by a single level. The bath Hamiltonian $H_B = H_t + H_{ph}$ is given as a sum of electron (lead) and phonon baths, where

$$H_t = \sum_{k \in L,R} \varepsilon_k a_k^\dagger a_k \tag{2}$$

represents the noninteracting leads Hamiltonian with fermionic creation/annihilation operators $a_k^\dagger a_k$, and

$$H_{ph} = \sum_j \hbar \omega_j \left( b_j^\dagger b_j + \frac{1}{2} \right) \tag{3}$$

represents the phonon bath with bosonic creation/annihilation bosonic operators $b_j^\dagger b_j$ for phonon mode $\omega_j$.

The coupling between the system and the baths is given by

$$V_{SB} = \sum_{k \in L,R} (\Delta_k d_k^\dagger a_k + \Delta_k^* a_k^\dagger d_k^\dagger d) + d^\dagger d \sum_j M_j (b_j^\dagger + b_j), \tag{4}$$

where $\Delta_k$ is the hopping term between the system and the leads, and $M_j$ is the strength of the electron-phonon couplings to mode $j$. The former is determined from the relation

$$\Gamma_{L,R}(\varepsilon) = 2\pi \sum_{k \in L,R} |\varepsilon_k|^2 \delta(\varepsilon - \varepsilon_k), \tag{5}$$

where $\Gamma_{L,R}(\varepsilon) = \frac{\omega_c}{\pi} \sqrt{4b^2 - (\varepsilon - \mu_{L,R})^2}$ is used to mimic a tight-binding chain and $\mu_{L,R}$ is the chemical potential of the left/right lead, respectively. We adopt the same parameters for $H_B(\varepsilon)$ used in our recent studies [57,64], namely, $a = 0.2$ eV and $b = 1$ eV. For this choice, $\Gamma = 0.16$ eV is the maximum value of $\Gamma_B(\varepsilon) + \Gamma_L(\varepsilon)$. The electron-phonon couplings $M_j$ are determined from the relation

$$J(\omega) = \pi \sum_j M_j^2 \delta(\hbar \omega - \hbar \omega_j), \tag{6}$$

where we follow the notation of Caldeira and Leggett [66] for the phonon spectral density

$$J(\omega) = \frac{\pi \hbar^2}{2 \hbar} (\omega^2 / \omega_{s}^{(1)}) e^{-\frac{\omega}{\lambda \omega_{s}}} \tag{7}$$

In the above equation, the dimensionless Kondo parameter $\eta = \frac{\pi m}{\hbar} s \frac{\omega_{s}^{(1)}}{\omega_{s}}$ determines the overall strength of the electron-phonon couplings, $\omega_s$ is the characteristic phonon bath frequency, and $\Gamma(s)$ is the Euler Gamma function. For future reference, we introduce an additional parameter $\lambda = \sum_j \frac{M_j^2}{\hbar \omega_j} = \frac{1}{\pi} \int \frac{d\omega}{\hbar} J(\omega)$, which is known as the reorganization energy (or polaron shift). Figure 1 shows the results for $J(\omega)$ for different values of $s$.

The model introduced above and variants thereof have been widely used to study nonequilibrium charge transport in nanostructures, such as, for example, semiconductor quantum dots [67], carbon nanotubes [68], or molecular junctions [50,69–73]. In the latter case, the phonons may include, in addition to the phonons of the contacts, the vibrational degrees of freedom of the molecule. In all previous studies, however, the spectral density was limited to the Ohmic case, for which $s = 1$. The sub-Ohmic ($s < 1$) and super-Ohmic ($s > 1$) limits, which play an important role in the related spin-boson model [4], have not been studied in transport junctions.
The reduced density matrix formalism

The density generated by the above Hamiltonian are rich and rather complicated to solve. Numerically exact techniques include real time path integrations [43,58,61,74–79] and the ML-MCTDHF approach [20–22]. Both are limited to relatively short times and cannot describe the dynamics on all relevant timescales. Recently, we have proposed to combine a numerically exact impurity solver with a reduced density matrix formalism [57,62–64,80]. Application to the above model for the Ohmic spectral density uncovered a fascinating behavior with rich dynamics on multiple timescales and bistability depending on the choice of initial conditions and vanishes for an empty dot.

More details can be found in Ref. [57].

**III. REDUCED DENSITY MATRIX FORMALISM**

The basic quantity of interest is the reduced density matrix \( \rho(t) \), which is derived from the full density matrix \( \rho(t) \) by the application of the projection operator \( P = \rho_B T_R \). Here, the index \( B \) refers to the bath degrees of freedom or the “irrelevant” part of the full Hamiltonian. \( \sigma(t) = T_R \rho(t) \) obeys a generalized quantum master equation, given by [81]

\[
\frac{\partial}{\partial t} \sigma(t) = \mathcal{L}_S \sigma(t) + \vartheta(t) - \frac{i}{\hbar} \int_0^t d\tau \kappa(\tau) \sigma(t - \tau),
\]

where \( \mathcal{L}_S = \{ H_S, \ldots \} \) is the system’s Liouvillian. The function

\[
\vartheta(t) = T_R \mathcal{L}_V e^{-\frac{\mathcal{L}_O}{\hbar} Q} \rho(0)
\]

depends on the choice of initial conditions and vanishes for an uncorrelated initial state (which is the case considered below), i.e., when \( \rho(0) = \sigma(0) \otimes \rho_B(0) \), where \( \sigma(0) \) and \( \rho_B(0) \) are the system and bath initial density matrices, respectively, and \( \mathcal{L}_V = \{ V_{SB}, \ldots \} \). We consider two initial conditions for \( \sigma(0) \), an occupied and an unoccupied dot. We assume a noncorrelated initial state for \( \rho_B(0) \),

\[
\rho_B(0) = \rho_{ph}(0) \otimes \rho_L^{\uparrow}(0) \otimes \rho_R^{\downarrow}(0),
\]

where \( \beta = \frac{1}{k_B T} \) is the inverse temperature.

\[
\rho_{ph}(0) = \exp \left[ \sum_{k \in L/R} \frac{\hbar \omega_k}{2} a_k^{\dagger} a_k \right]
\]

is the initial density matrix for the leads, and

\[
\rho_{L/R}^{\uparrow/\downarrow}(0) = \exp \left[ -\beta \sum_{j} b_j^{\dagger} b_j + \frac{1}{2} \right]
\]

represents the initial density matrix of the phonon bath. We also consider two different initial conditions for the phonons, one where \( \delta_j = 0 \) in Eq. (12) corresponding to phonons initially equilibrated with an unoccupied dot and another where \( \delta_j = 1 \) corresponding to phonons equilibrated to an occupied dot. More details can be found in Ref. [57].

The calculations of the memory kernel in Eq. (8), \( \kappa(t) \), is the tricky part. Formally it is given by

\[
\kappa(t) = T_R \mathcal{L}_V e^{-\frac{\mathcal{L}_O}{\hbar} Q} \rho_B(0),
\]

where \( Q = 1 - P, P = \rho_B(0) T_R \{ \cdot \} \) and \( \mathcal{L} = \{ H, \ldots \} \). A more suitable form for the memory is given in terms of a Volterra equation of the second type, removing the complexity of the projected dynamics of Eq. (13):

\[
\kappa(t) = i \hbar \Phi(t) - \Phi(t) \mathcal{L}_S + \frac{i}{\hbar} \int_0^t d\tau \Phi(t - \tau) \kappa(\tau)
\]

with \( \Phi(t) = T_R \mathcal{L}_V e^{-\frac{\mathcal{L}_O}{\hbar} Q} \rho_B(0). \) For the present model, the coherence does not couple to the populations [57]. Thus, only the \( \Phi_{nn,mm} \) elements are required to obtain the populations. It can be shown [57] that only the dot-lead interactions in \( \mathcal{L}_V \) contribute to these elements:

\[
\Phi_{nn,mm}(t) = \frac{2}{\hbar} T_R \left\{ \rho_B |m \rangle \sum_k t_k \langle d(t) a_k^{\dagger} |m \rangle \right\}.
\]

Here, \( |m \rangle \) denotes the electronic state of the quantum dot, where \( m \) can take the values 1 or 0, corresponding to an occupied or an unoccupied dot, respectively. Previously, we have shown that \( \Phi_{nn,mm}(t) \) can be expressed in terms of the sum of the left \( I^L_m(t) \) and right \( I^R_m(t) \) currents:

\[
e \Phi_{nn,mm}(t) = I^L_m(t) + I^R_m(t),
\]

is the left/right current for an initial occupied \( (m = 1) \) or empty \( (m = 0) \) dot, and \( e \) is the electron charge.

While the calculation of the memory kernel requires a solution of the time-dependent left and right currents, it typically decays on timescales much faster than the density matrix itself [57,62] and thus is amenable to a numerically exact impurity solver. For this purpose we adopt the ML-MCTDHF approach [20–22] and calculate the memory up to a cutoff time \( t_c \), where \( t_c \) is large enough such that the results for the reduced density matrix do not change for large cutoff times. When suitable, i.e., for small electron-phonon couplings [64], we often use the nonequilibrium Green’s function formalism within the self-consistent Born approximation to generate the memory kernel for \( t < t_c \).

**IV. SUB-OHMIC AND OHMIC CASES**

In Fig. 2 we show the population dynamics for the Ohmic \( (s = 1) \) and sub-Ohmic \( (s = \frac{1}{2}) \) cases for various values of the reorganization parameter \( \lambda \) and the phonon frequency \( \omega_c \). Throughout this paper we fix the electronic parameters: dot energy \( \delta_d = 0.25 \) eV, applied bias voltage \( \mu_L = -\mu_R = 0.05 \) eV, and zero temperature \( (k_B T = 0) \). These parameters were chosen to ensure the existence of a bistability for the Ohmic case [64]. The results shown for the Ohmic case (left set of panels in Fig. 2) summarize our previous findings [57,64]. In short, the decay of the population is characterized by three distinct timescales. At short to intermediate times, the population dynamics are governed by the system-lead
FIG. 2. (Color online) Transient dynamics of the average quantum dot population for the Ohmic (left set of panels, \( s = 1/2 \)) and sub-Ohmic case (right set of panels, \( s = 1/2 \)). The results are shown for all four initial conditions: Black and red curves correspond to the unoccupied/occupied dot at phonon initial condition \( \delta_j = 0 \), whereas blue and green curves correspond to the unoccupied/occupied dot at \( \delta_j = 1 \), respectively. In all results the cutoff time used to generate the memory kernel is \( t_c = 100 \text{ fs} \).

hybridization \( \hbar/\Gamma \) (as clearly seen for \( \delta_j = 0, \lambda = 1000 \text{ cm}^{-1} \)) or by \( \omega_c^{-1} \) (as clearly seen for \( \delta_j = 1, \lambda = 1000 \text{ cm}^{-1} \)). In addition to the short and intermediate timescales associated with the separate electronic and phononic degrees of freedom, the electron-phonon coupling introduces longer timescales related to the tunneling between the two charge states, as clearly evident for increasing values of \( \lambda \). On a timescale longer than this tunneling time, the population is characterized by two distinct long-lived solutions for large values of \( \lambda \). This “bistability” vanishes as the system become less adiabatic (increasing \( \omega_c \)) or for small polaron shifts (small \( \lambda \)).

The situation is similar for the sub-Ohmic case (right set of panels in Fig. 2). All three timescales are clearly observed even for \( s = 1 \). For \( \lambda = 1000 \text{ cm}^{-1} < \epsilon_d \), the more stable solution is associated with the nonshifted configuration \( \delta_j = 0 \), and the system relaxes to a single long-lived state regardless of the choice of initial condition \( \delta_j = 0 \text{ or } 1 \). The dynamics at short and intermediate times are governed by \( \hbar/\Gamma \) for the nonshifted phonon bath \( \delta_j = 0 \), since the dot energy \( \epsilon_d = 0.25 \text{ eV} \) is outside the conduction window \( (\Delta \mu = 0.1 \text{ eV}) \), and thus the system remains in the uncharged state. This is not the case for the shifted bath initial preparation \( \delta_j = 1 \). Since the effective dot energy \( \epsilon_d = \epsilon_d - 2\lambda \text{, Ref. [64]} \) is within the conduction window, we observe a rapid uncharging decay associated with \( \hbar/\Gamma \) followed by a slower relaxation to the stable uncharged configuration along the generalized bath mode, characterized by \( 1/\omega_c \) timescale.

As \( \lambda \) increases above \( \epsilon_d \), the long-time behavior of the population depends on the choice of the initial phonon preparation, leading to a bistability (two distinct long-lived solutions). The bistability is rather sensitive to the characteristic phonon frequency and can lead to two steady state solutions in the adiabatic limit, as \( \omega_c \to 0 \) [54]. As \( \omega_c \) increases the bistability gradually disappears. Comparing the sub-Ohmic case to the Ohmic case, the bistability persists over a wider range of frequencies and polaron shifts for \( s < 1 \). This can be explained qualitatively by looking at the spectral density function shown in Fig. 1. In the sub-Ohmic case, the bath spectrum is shifted to the lower frequency end as compared with the Ohmic case that has the same characteristic frequency \( \omega_c \). Thus, a comparison of the dynamics generated for the Ohmic case at particular values of \( \omega_c \) should be done with the dynamics generated for the sub-Ohmic case \( (s = 1/2) \) for a higher \( \omega_c \).

To summarize the sub-Ohmic case, we find that the behavior is similar to the Ohmic case. The major difference is observed for the long time relaxation. The sub-Ohmic case shows a pronounced bistability at larger values of \( \omega_c \) and a wider range of polaron shifts compared to the Ohmic case, resulting from the increase in the density of low frequency modes as \( s \) is decreased below 1.

V. SUPER-OHMIC CASE

The trends observed going from the sub-Ohmic case to the Ohmic case continue smoothly as \( s \) is increased above 1. In Fig. 3 we plot the transient population dynamics for the super-Ohmic case \( (s = 2 \text{ and } s = 3) \) for the same set of frequencies and polaron shifts shown in Fig. 2. In two cases, we are unable to converge the results based on the memory formalism with the given input and thus show the direct calculations based on the ML-MCTDH-SQR approach generated for \( t < t_c = 100 \text{ fs} \). Similar to the sub-Ohmic case, for \( \lambda = 1000 \text{ cm}^{-1} \) the population dynamics at short and intermediate times is governed by \( \hbar/\Gamma \) for the nonshifted phonon bath \( \delta_j = 0 \) and by the typical phonon frequency for the shifted bath initial preparation \( \delta_j = 1 \). The major effect associated with changing \( s \) is the change in the characteristic phonon frequency, given by \( \omega_{\text{so}} \). As \( s \) increases above 1, the characteristic frequency increases leading to a rapid decay of the population at intermediate times, evident in Figs. 2 and 3. Concerning the long time behavior, we find that the tunneling dynamics are washed out as \( s \) increases above 1 and the bistability is limited to a narrower range of polaron shifts, which eventually disappears for \( s \geq 3 \) for the range of frequencies studied.
Comparing the behavior of the bistability to the localization transition in the spin-boson model, it is clear that the origin of the two phenomena is quite different. While in the spin-boson model localization is a quantum phase transition, observed strictly at zero temperature and zero bias, bistability is a dynamical phenomenon observed in the time domain. Furthermore, while localization vanishes for $s > 1$, the bistability transitions smoothly across the Ohmic case. Moreover, the two phenomena differ and show opposing behavior with respect to the dependence on $\omega_c$ and to a large extent with respect to the polaron shift $\lambda$. For the latter, the bistability is limited to a certain window of $\lambda$, a window which smoothly narrows down as $s$ increases. Localization in the spin-boson model persists above a certain value of $\lambda$.

A notable feature of the super-Ohmic case is the pronounced oscillations in the population compared to the over-damped Ohmic and sub-Ohmic behavior, as shown in the left panels of Fig. 4. This is similar to the coherent dynamics observed for the super-Ohmic case in the spin-boson model. The period of oscillations increases as the characteristic frequency of the phonon bath decreases, which makes the convergence of the memory formalism difficult for $\omega_c$ values between 100 and $500 \text{ cm}^{-1}$ due to the relatively long transient dynamics. As $\omega_c$ increases, the coherence is eventually quenched because of the more efficient energy exchange between the electron and phonon degrees of freedom, as shown in Fig. 5.

To understand this behavior, we propose examining the phonon bath autocorrelation function given by

$$\langle \cos(\omega_c t) \rangle_{\text{av}}.$$
Using the spectral density of Eq. (6), we obtain an exact solution for the dot population for different characteristic frequencies $\omega_c$ of the phonon bath as indicated in Fig. 5. The color code is the same as in Fig. 4. In the plot and for four different initial conditions as indicated by the different colors. The color code is the same as in Fig. 4.

(at $T = 0$)

$$\alpha(t) = \frac{1}{\hbar \pi} \int_0^\infty d\omega J(\omega) \exp(-i\omega t). \quad (18)$$

Using the spectral density of Eq. (6), we obtain an exact solution for $\alpha(t)$ of the form

$$\alpha(t) = \frac{\eta \omega_c^2}{2} \frac{\Gamma(1+s)}{\Gamma(1+s)(1 + \tau^2 \omega_c^2)^{1/2}} \exp[-i(1+s)\arctan(\omega_c t)]. \quad (19)$$

In the right panels in Fig. 4 we plot the imaginary part of $\alpha(t)$ for two values of the frequency and for different values of $s$. $\alpha(t)$ shows a transition from a smooth function of time at small values of $s < 1$ to an oscillatory function at larger values of $s > 1$. The origin of this oscillatory behavior is in the term $\exp[i(1+s)\arctan(\omega_c t)]$ and is correlated with the under-damped dynamics of the phonon bath as indicated in the left panels of Fig. 4.

A more quantitative picture of the oscillatory behavior emerges by considering the dynamics of the reaction mode $\langle Q(t) \rangle = \sum_{\alpha \beta} M_{\alpha \beta} n_\alpha n_\beta \langle \delta j_{\alpha \beta} \rangle$ [65]. Despite the fact that the dynamics of the phonons have been traced out by considering the reduced density matrix of the system alone, $\langle Q(t) \rangle$ for the nonshifted case ($\delta_j = 0$) can be inferred using its equation of motion, resulting in [65]

$$\langle Q(t) \rangle = \langle Q_1(t) \rangle + \langle Q_2(t) \rangle \quad (20)$$

with

$$\langle Q_1(t) \rangle = n_\infty \sqrt{\frac{2}{\alpha(0) \delta^2}} \int_0^t \alpha(\tau)d\tau \quad (21)$$

$$\langle Q_2(t) \rangle = \frac{2}{\alpha(0) \delta^2} \frac{\delta n(t) \alpha(t - \tau)d\tau}{}, \quad (22)$$

where $n_\infty$ is the steady state dot population and $\delta n(t) = \langle d(t)d(t) \rangle - n_\infty$. A similar expression not given here can be derived for the shifted case ($\delta_j = 1$) (see Appendix). The first term $Q_1$ on the right hand side of Eq. (20) describes the relaxation of the reaction mode due to the coupling to the phonon bath in the absence of coupling to the leads. It can be calculated explicitly using Eq. (19), resulting in

$$Q_1(t) = n_\infty \sqrt{\frac{2\lambda}{\hbar \omega_c}} \left( \frac{\cos(s \arctan(\omega_c t))}{(1 + \tau^2 \omega_c^2)^{1/2}} - 1 \right), \quad (23)$$

where the relations $2\alpha(0) = \eta \omega_c^2 \Gamma(1+s)$, $\int_0^\infty \alpha(\tau)d\tau = -i\lambda/\hbar$, and $\eta = 2\lambda/(\hbar \omega_c \Gamma(s))$ were used. The second term $Q_2(t)$ includes the influence of the coupling to the leads on the dynamics of the reaction mode. The long-time limit of the reaction mode is determined by the first term in Eq. (20), i.e.,

$$\lim_{t \rightarrow \infty} \langle Q(t) \rangle = \lim_{t \rightarrow \infty} Q_1(t) = -n_\infty \sqrt{\frac{2\lambda}{\hbar \omega_c}}. \quad (24)$$

In Fig. 6 we plot the dynamics of the reaction mode for the same parameters used to generate the data in the left set of panels in Fig. 4 for both the sub-Ohmic and super-Ohmic cases. Note that in both figures we are unable to converge the results for $s = 1$ beyond the cutoff time $t_c = 100$ fs (see the discussion above). For $s \leq 1$, the reaction coordinate $\langle Q(t) \rangle$ decays monotonically to its steady state value if it is initially in equilibrium with the electronic state of the dot (full black and green lines). The timescale governing this decay can either be purely phononic, arising from the term $\langle Q_2(t) \rangle$ with algebraic relaxation characteristics given by $\sim(1 + \tau^2 \omega_c^2)^{-s}$, or associated with the relaxation of the electronic population $\delta n(t)$ arising from the term $\langle Q_1(t) \rangle$. For $s = 1$, the decay of $\langle Q(t) \rangle$ is significantly slower than that of $\delta n(t)$ and thus is determined by the slower phononic dynamics, while for $s = 1$ there is no clear time scale separation. In the case of a
preparation, where the phonon degrees of freedom are initially not in equilibrium with the electronic state of the dot (full red and blue lines), a more complex transient dynamics is seen, which involves electronic and phononic contributions and timescales.

In both cases ($s = \frac{1}{2}$ and 1), the dot population assumes for longer times two distinct values depending on the initial conditions for the phonon bath, i.e., exhibits bistability, as clearly evident in Fig. 4. The bistability in the dot populations leads to two solutions for $\langle Q(t) \rangle$. In the long-time limit, the difference between the solutions for $\langle Q(t) \rangle$, obtained for shifted and unshifted initial preparation, is related to the corresponding difference of the dot population $\Delta n_d$ by [65,82]

$$\Delta Q = -\frac{\lambda}{\hbar} \sqrt{\frac{2}{\alpha(0)}} \Delta n_d = -\sqrt{\frac{2\lambda}{\hbar \omega_c}} \Delta n_d, \quad (25)$$

This relation between $\Delta n_d$ and $\Delta Q$ is only valid in the steady state and can therefore be used as a consistency check if the steady state has been reached. For the results in Fig. 6 it is fulfilled.

As $s$ is increased above 1 the picture changes qualitatively. First, the bistability gradually disappears as discussed in details above. This implies that $\langle Q(t \rightarrow \infty) \rangle$ assumes a unique value regardless of the initial preparation of the phonons. Second, as clearly evident in Fig. 6, $\langle Q(t) \rangle$ shows a pronounced oscillatory behavior correlated with the oscillations observed in the dot population shown in Fig. 4. Most interestingly, for the unshifted initial phonon preparation ($\delta_j = 0$), the oscillation in $\langle Q(t) \rangle$ lead to transient values for the reaction coordinate that are associated with the shifted position, and vice versa. This “exchange” of positions is also reflected, to a smaller extent, in the dot population shown in the corresponding panels of Fig. 4. For larger values of $s$ ($s > 1$), the bare phonon relaxation time scale $\sim (1 + r^2 \omega_c^2)^{-\frac{1}{2}}$ is significantly faster than the electronic dynamics $\delta n(t)$, and thus the latter dominates the dynamics of the reaction mode $\langle Q(t) \rangle$ for longer times.

VI. CONCLUSIONS

In this paper we have studied the role of the spectral density of the phonon bath on the relaxation dynamics and bistability in the nonequilibrium extended Holstein model. To this end, sub-Ohmic, Ohmic, and super-Ohmic spectral densities were considered. The results show a physically rich behavior, including a transition from incoherent to oscillatory dynamics and a disappearance of bistability signatures upon increase of the power $s$ of the spectral density. Some features observed for the sub- and super-Ohmic cases can be rationalized qualitatively by rescaling the characteristic phonon frequency $\omega_c \rightarrow s \omega_c$. For example, the bistability which is exemplified in the adiabatic limit $\omega_c \rightarrow 0$ persists over a larger range of frequencies for sub-Ohmic spectral density while the opposite is true for the super-Ohmic case. However, the appearance of a slow algebraic decay for $\langle Q(t) \rangle$ in the sub-Ohmic case as well as the oscillatory behavior of $\langle Q(t) \rangle$ in the super-Ohmic case cannot be explained by simple scaling arguments but require a more elaborate analysis in terms of the bath correlation function $\alpha(t)$ and are distinct from the Ohmic limit.

APPENDIX: REACTION COORDINATE

FORMAL SOLUTION

In this Appendix we describe the formal solution of the reaction coordinate $Q(t)$ for both initial conditions (for simplicity we set $\hbar = 1$). For the phonon Hamiltonian

$$H_{ph} = \sum_j \omega_j b_j \dagger b_j + d_d \sum_j M_j b_j \dagger b_j, \quad (A1)$$

the equation of motion for $b_j(t)$ reads

$$\dot{b}_j(t) = -i \omega_j b_j - i M_j d_d \quad (A2)$$

with the formal solution

$$b_j(t) = b_j(0)e^{-i\omega_j t} - i M_j \int_0^t n_d(\tau)e^{-i\omega_j(0-\tau)}d\tau. \quad (A3)$$

We will define the dimensionless average position of the phonon mode $j$ with $\langle x_j(t) \rangle = \frac{\langle b_j(t) + b_j(t)\rangle}{2\sqrt{\sum_i M_i^2}}$ and the corresponding reaction coordinate $\langle Q(t) \rangle = \frac{\langle \sum_i M_i b_i(t) \rangle}{\sqrt{2 \sum_j M_j^2}}$ such that

$$\langle Q(t) \rangle = \sqrt{\frac{2}{\sum_j M_j^2}} \langle x_j(t) \rangle. \quad (A4)$$

Using Eq. (A3) we find

$$\langle Q(t) \rangle = -\sqrt{\frac{2}{\sum_j M_j^2}} \sum_j M_j \cos \omega_j t \langle b_j(0) \rangle - \sqrt{2} \int_0^t \langle n_d(t) \rangle \sum_j M_j^2 \sin \omega_j (t - \tau) d\tau. \quad (A5)$$

The equation above can be rewritten in terms of the bath autocorrelation function given in Eq. (18) using the relations

$$\sum_j M_j^2 e^{-i\omega_j t} = \frac{1}{\pi} \int_0^\infty \pi \sum_j M_j^2 \delta(\omega - \omega_j)e^{-i\omega t} d\omega = \frac{1}{\pi} \int_0^\infty J(\omega)e^{-i\omega t} d\omega = \alpha(t)$$

and

$$\sum_j \frac{M_j^2}{\alpha_j} e^{-i\omega_j t} = -i \int_0^t d\tau \alpha(t) + \lambda \quad (A6)$$
to reduce the formal solution of \(\langle Q(t) \rangle\) into

\[
\langle Q(t) \rangle = \sqrt{\frac{2}{\alpha(0)}} \int_0^t \delta n(\tau) \alpha(t - \tau) d\tau + \sqrt{\frac{2}{\alpha(0)}} n_\infty \int_0^t \alpha(\tau) d\tau.
\]

(A7)

The equation above corresponds to the nonshifted bath initial condition, i.e., \(\langle b_j(0) \rangle = 0\), while for the shifted-bath (\(\langle b_j(0) \rangle = -\frac{\alpha(0)}{\omega_c}\)) the solution reads:

\[
\langle Q(t) \rangle = -\sqrt{\frac{2}{\alpha(0)}} \lambda + \sqrt{\frac{2}{\alpha(0)}} \Im \left\{ \int_0^t d\tau \alpha(\tau) \right\} + \sqrt{\frac{2}{\alpha(0)}} \int_0^t \delta n(\tau) \alpha(t - \tau) d\tau + \sqrt{\frac{2}{\alpha(0)}} n_\infty \int_0^t \alpha(\tau) d\tau.
\]

(A8)

In the above \(\delta n(t) = \langle n_d(t) \rangle - n_\infty\) with \(n_\infty = \lim_{t \to \infty} \langle n_d(t) \rangle\), and \(\Im \{\langle \ldots \rangle\} \) are the real and imaginary parts, respectively.

In steady state limit, we can use the fact that \(\lim_{t \to \infty} \sqrt{\frac{2}{\alpha(0)}} \int_0^t \delta n(\tau) \alpha(t - \tau) d\tau \to 0\) since \(\delta n(\tau)\) and \(\alpha(\tau)\) approach zero for \(\tau \to \infty\) and

\[
\int_0^\infty \alpha(\tau) d\tau = -i\lambda
\]

(A9)

to obtain

\[
\Delta Q = -\sqrt{\frac{2}{s\lambda \omega_c}} \Delta n
\]

(A10)

\[
= -\sqrt{\frac{2\lambda}{s\omega_c}} \Delta n,
\]

(A11)

where \(\Delta Q\) and \(\Delta n_d\) are the steady state difference between the shifted and the nonshifted phonon bath for the reaction coordinate and the dot population, respectively.
