Abstract

Background: Climate extremes are likely to become more common in the future and are expected to change ecosystem processes and functions. As important consumers of seeds in forests, rodents are likely to affect forest regeneration following an extreme weather event. In April 2015, we began a field experiment after an extreme snowfall event in January 2015 in a primary forest that was > 300 years old. The heavy snow broke many tree limbs, which presumably reduced the numbers of seeds produced. Two treatments (rodent exclusion and rodent access) were established in the forest, in which rodent exclusion were achieved by placing stainlessness nets around the plot borders. Plant abundance, plant species richness, soil properties, soil microbial community composition, basal and substrate-induced respiration were determined in December 2017.

Results: Plant abundance and species richness significantly increased, but soil microbial biomass decreased with rodent exclusion. Urease activity and soil basal respiration also significantly decreased with rodent exclusion. Most other soil properties, however, were unaffected by rodent exclusion. The relative effects of multiple predictors of basal respiration were mainly explained by the composition of the soil microbial community.

Conclusions: After a heavy snowfall in an old-growth forest, exclusion of rodents increased plant regeneration and reduced microbial biomass and soil basal respiration. The main factor associated with the reduction in soil basal respiration was the change in the composition of the soil microbial community. These findings suggest that after a heavy snowfall, rodents may interfere with forest regeneration by directly reducing plant diversity and abundance but may enhance carbon retention by indirectly altering the soil microbial community.

Introduction

Forests cover about 4 billion ha worldwide and provide important ecosystem goods and functions (Fei et al. 2018; Jactel et al. 2018; Keenan et al. 2015). In particular, the net global forest carbon sink was estimated to be 1.1 Pg year⁻¹, with the largest uncertainties in tropical forests (Pan et al. 2011). Because primary forests account for more than one-third of the total forest area on the planet and because tropical/subtropical forests represent nearly half of the primary forest area (Luyssaert et al. 2008; Morales-Hidalgo et al. 2015), understanding the carbon dynamics in tropical/subtropical primary forests is important. Climate extremes (such as droughts, heatwaves, and rainstorms) are expected to become more common in the future (Kayler et al. 2015; Reyer et al. 2015). Although the high productivity and biodiversity...
of primary forests may help mitigate climate change and climate extremes (Stephenson et al. 2014; Zhou et al. 2006), our understanding of the responses of above- and belowground properties to climate extremes remains limited in primary forest ecosystems.

Among the climate extremes, extreme snowfall events are likely to have substantial effects on forest ecosystems (Ashley et al. 2020; Zhao et al. 2016). Previous relevant studies mainly focused on boreal and temperate forests because such forests frequently experience heavy snow loads in the winter (Ashley et al. 2020; Venalainen et al. 2020). Heavy snowfall, for example, frequently causes substantial damage (including the breaking of stems and uprooting of trees) in Finnish forests (Lehtonen et al. 2016). In boreal forests, a snowfall mass of 20–40 kg m$^{-2}$ is sufficient to break the stems of Scots pine and Norway spruce (Peltola et al. 1997). Forest canopies composed of mixed tree species are apparently more vulnerable to snow damage than forest canopies composed of one tree species (Díaz-Yanez et al. 2017). In addition, the snowpack in winter can also change soil carbon emission by affecting soil temperature and moisture (Contosta et al. 2016). Consistent with the latter result, a meta-analysis revealed that an increase in snowpack depth can increase soil respiration and microbial biomass by increasing soil temperature and water content (Li et al. 2016).

For subtropical forest ecosystems, snowstorms are rare but can occur given climate change (Zhao et al. 2016; Zhou et al. 2013). An anomalous extreme snow storm in 2008 caused a substantial disturbance to subtropical forest ecosystems (Zhou et al. 2013). After another snow storm in a subtropical forest, researchers found that tree mortality exceeded seed recruitment and that evergreen broad-leaved species were more susceptible than deciduous broad-leaved species (Ge et al. 2015). In addition, snow storms can enhance canopy gaps that facilitate light penetration to the forest floor and thereby increase germination and invasion by non-native herbaceous species (Song et al. 2017b). By increasing the sizes of canopy gaps in another subtropical forest, snow storms also decreased soil organic carbon and nutrient contents (Xu et al. 2016). Using an eddy covariance technique, researchers recently found that, although a snow storm strongly decreased the carbon sink in a primary subtropical forest (Song et al. 2017a), the net carbon uptake was quickly restored in the following year, suggesting that forest ecosystems are highly resilient in their responses to extreme weather events (Reyer et al. 2015; Song et al. 2017a). These previous studies have demonstrated that extreme weather events can greatly affect above- and belowground organisms and processes (Bardgett and Caruso 2020; Bardgett and van der Putten 2014). Understanding those factors may increase our understanding of above- and belowground food webs, including the relationships among predators, plants, and soil functions (Mundim and Bruna 2016; Sitters and Venterink 2015).

Mammalian herbivores can affect soil nutrient cycling by grazing on aboveground plant tissues in grassland ecosystems (Bardgett and Wardle 2003). How climate change-driven alterations in the relationships between plants and herbivores/“seed predators”, i.e., animals that consume seeds, can affect soil carbon and nutrients in forest ecosystems is still unclear. In primary forests, regeneration and recruitment of plants were strongly regulated by the activities of scatter-hoarding rodents, who can damage seedlings and can eat, remove, and cache plant seeds (Boone and Mortelliti 2019; Cao et al. 2016; Wang et al. 2013a, b). When snow storms decreased seed production, seed predators may alter its feeding preference and thereby substantially influence seed dispersal (Zhou et al. 2013). The changes in the interactions between seeds and seed predators induced by climate extremes may also affect soil microbial communities and soil carbon emission in primary forest ecosystems (Mundim and Bruna 2016). If these interactions increase soil carbon emissions, they could result in a positive feedback loop between soil carbon emissions and climate change.

In the present study, we conducted a field experiment with two treatments in April 2015 after an extreme snowfall event in January 2015. The extreme snowfall event was the largest record during past 40 years, which covered half-meter on the floor (Song et al. 2017b). The experimental site was a primary subtropical evergreen broadleaved forest that was > 300 years old (Tan et al. 2011). The treatments (± rodent exclusion) were applied to the replicated plots. As described in a conceptual diagram (Fig. 1), we hypothesized that exclusion of rodents would increase plant abundance and plant species richness, which would increase carbon input into the soil in the form of litter and rhizodeposition; the increased carbon input would increase soil carbon content but would also increase soil microbial activity and biomass, which would increase soil carbon emissions.

**Materials and methods**

**Study site**

The experiment was conducted at the Ailaoshan National Nature Reserve (101°01′E, 24°32′N, 2450 m a.s.l.), Yunnan Province, Southwestern China. The area has a typical subtropical monsoon climate, with a mean annual precipitation of 1840 mm and a mean annual temperature of 11.3 °C. The forest has a loamy alfisol. As noted earlier, the evergreen broadleaved forest in this study was > 300 year old and occupied a protected area of 5110 ha. The average tree height was 20 m, and the average tree density was 2728 per ha. The mean soil organic carbon content was 116 g kg$^{-1}$, the mean soil total
nitrogen content was 7 g kg\(^{-1}\); and the mean soil pH was 4.2. The dominant tree species included *Castanopsis rufescens*, *Castanopsis wattii*, *Hartia sinensis*, *Lithocarpus chintungensis*, *Lithocarpus hancei*, *Lithocarpus xylocarpus*, and *Vaccinium ducluoxii* (Song et al. 2017a; Tan et al. 2011). The dominant rodent species included *Apodemus draco*, *Apodemus latronum*, and *Niviventer fulvescens*. An anomalous extreme snowfall event occurred in January 2015; it resulted in a snow depth on the forest floor of 50 cm. It also caused substantial damage to tree limbs and branches, and a substantial increase in the openness of the canopy (Song et al. 2017b).

**Experimental design**

We began the experiment in April 2015 at which time the primary forest had experienced 3 months with a substantial snowpack following the heavy snow in January. We randomly selected 24 pairs of plots (a total of 48 plots) from established 194 pairs of circular field plots, each measuring 1.3 m in diameter. Rodent exclusion plots were surrounded with a stainless steel mesh that was 1.3 m in height above ground and that extended 10 cm into the soil. The 1-cm openings in the mesh were sufficient to exclude rodents but presumably had minimal effects on light, air, and moisture penetration. Rodent “access” plots were not surrounded with stainless steel mesh and were adjacent to rodent exclusion plots. Each pair of plots (± mesh, i.e., ± rodent exclusion) represented one replicate. The two plots in a replicate were less than 1 m apart, and replicate pairs were separated by ≥10 m and were randomly arranged under the forest canopy as shown in Supplementary Material Figure S1.

Plant properties, soil properties, and microbial properties were assessed in December 2017. For plant properties, we determined the species of all woody plants taller than 5 cm within a 1 m × 1 m subplot in each plot; the data were used to determine plant richness and plant abundance in plots with and without rodent exclusion. In addition, three soil cores (3-cm diameter) were collected at depths of 0–10 cm; the cores were collected...
from the center of each plot to account for any heterogeneity resulting from position. Plant litter was removed from the soil surface before the cores were taken. The three cores were combined to form one composite soil sample per plot. Fresh soils were passed through a 2-mm sieve, and remaining roots and stones were removed by hand. Soil samples were divided in half; one half was used for determination of soil physico-chemical characteristics, and the other half was used for phospholipid fatty acid (PLFA) analysis.

For physico-chemical analyses, soil samples were air dried, ground, and passed through a 0.25-cm sieve. Soil water content was measured by comparing weights before and after oven-drying at 105 °C for 24 h. Soil pH was determined using a 1:2.5 ratio of soil mass to deionized water volume. Soil organic carbon and dissolved organic carbon (after extraction with 0.5 mol L⁻¹ K₂SO₄) were measured with an elemental analyzer (vario TOC, Elementar Analysensysteme GmbH, Langenselbold, Germany). Total soil nitrogen was measured after micro-Kjeldahl digestion (CleverChem380, DeChemTech. GmbH, Hamburg, Germany). Soil nitrate and ammonium concentrations were determined with a chemical analyzer (CleverChem380, DeChem-Tech. GmbH, Hamburg, Germany) after digestion in 1 mol L⁻¹ KCl. The activities of cellulase, succrose, and urease were measured using a modified fluorescent-linked substrate microplate protocol with the situ soil pH conditions and the laboratory temperature (Liu 1996).

Soil microbial communities as indicated by PLFAs were examined as described by (Frostegård and Bååth 1996). Different PLFAs were used to represent different groups of soil microorganisms. Bacterial PLFAs were represented by i15:0, a15:0, 15:0, i16:0, 16:1ω9c, 17:0, a17:0, 17:1ω8c, 17:0, cy17:0, 18:1ω7c, and cy19:0; fungal PLFAs were represented by the PLFAs 18:1ω9c, 18:2ω6, and 18:3ω6 (Frostegård et al. 2011; Frostegård and Bååth 1996). The ratio of fungal PLFAs to bacterial PLFAs (F:B) was used to estimate the microbial community composition in soil (Bardgett et al. 1996). All of the PLFAs were indicated by MIDI peak identification software (MIDI, Inc., Newark, DE, USA).

Soil basal respiration and substrate-induced respiration were measured with a microcosm experiment modified from Wardle and Zackrisson (2005). In brief, a 5-g (dry weight) subsample of fresh soil from each of 12 randomly selected plots with and without rodent exclusion was placed in a 228-mL glass bottle, and the soil moisture was adjusted to 100% of water holding capacity to eliminate water limitation. For each treatment (± rodent exclusion), 6 bottles were amended with 5 mg of glucose and 6 bottles were not amended with glucose. The bottles were sealed and incubated at room temperature (25 °C). After 0 and 2 h of incubation, headspace CO₂ concentration was measured with a gas chromatograph (GC-2014, Shimadzu, Japan).

### Statistical analyses

T-test was used to determine the effect of rodent exclusion on plant properties, soil properties, soil enzymes, and soil microbial community with stats package in R. The normality and heterogeneity were tested before T-test. Data was made a Log-transformation when data did not fit the standard. Multiple regression models were used to determine the total effects of plants (species richness and abundance), soil enzyme activity (urease, sucrose, and cellulase), soil properties (soil organic carbon, soil total nitrogen, NO₃⁻-N, NH₄⁺-N, pH, soil water content, and dissolved organic carbon) and soil microorganisms (community, soil bacterial, and soil fungal PLFAs) on the variance in basal respiration. We first deleted the collinear variables and subsequently constructed a full model based on the standard with ΔAIC < 2 with MuMIn and performance packages in R. The parameter coefficients were used to calculate the relative effect of each predictor on basal respiration. All statistical analyses were performed with R version 3.3.2 (R Core Team 2016).

### Results

#### Responses of plants and soil properties to rodent exclusion

Plant abundance ($T = 2.72, P = 0.01$, Fig. 2a) and plant species richness ($T = 2.47, P = 0.02$, Fig. 2b) were significantly greater with rodent exclusion than without rodent exclusion. Abundance increased by 59%, and richness increased by 31% when rodents were excluded.

Soil organic carbon content and most soil properties were not significantly affected by rodent exclusion (Table 1). Rodent exclusion, however, significantly decreased urease activity (Table 1). Bacterial PLFAs ($T = 4.07, P = 0.001$, Fig. 3a), fungal PLFAs ($T = 3.17, P = 0.006$, Fig. 3b), and total PLFAs ($T = 3.95, P = 0.001$, Fig. 3d) were significantly lower in the rodent exclusion plots than in the plots without exclusion. Relative to the non-exclusion plots, rodent exclusion reduced numbers of bacterial, fungal, and total PLFAs by 19%, 21%, and 17%, respectively. In contrast, the ratio of fungi to bacteria ($T = 2.83, P = 0.01$, Fig. 3c) was significantly higher with than without rodent exclusion.

#### Responses of soil basal respiration to rodent exclusion

Basal respiration ($T = 4.87, P = 0.005$, Fig. 4a) was significantly lower (by 15%) with than without rodent exclusion. Substrate-induced respiration ($T = 0.34, P = 0.75$, Fig. 4b) was not significantly affected by rodent exclusion. The ratio of basal respiration to substrate-induced respiration was significantly lower with than without rodent exclusion ($T = 3.21, P = 0.02$, Fig. 4c).

A multiple regression model indicated that most of the variance in basal respiration was explained by soil...
properties and soil microbial properties and especially by the microbial community composition (ratio of fungi to bacteria) (Fig. 5). The total effects of plant properties and soil enzymes on basal respiration were marginal.

**Discussion**

Rodents strongly affect plant regeneration and community composition in forest ecosystems by their scatter-hoarding of seeds and by changing plant–plant interactions (Kang et al. 2020; Yang et al. 2020). In the current study, we examined the indirect effects of rodents on carbon emission from soil after a heavy snowfall. Heavy snowfalls can reduce seed production by breaking branches and limbs. Consequently, plant–predator (seed consumer) interactions would be altered (Mundim and Bruna 2016) and increase the percentage of seeds consumed by predators (Zhou et al. 2013). Consistent with our hypothesis, plant abundance and species richness were significantly enhanced by rodent exclusion. Based on the increase in plant regeneration, we expected that exclusion would increase carbon input into the soil and increase soil organic carbon content given the tight linkages between above- and belowground systems (Bardgett and Wardle 2003; Wardle and Zackrisson 2005). However, soil organic carbon content was not significantly increased by rodent exclusion (Table 1). The failure of rodent exclusion to increase soil organic carbon content might be explained by the high levels carbon in the soil of our study site. Also, our study covered only 3 years; perhaps a longer study would have revealed a positive
Table 1 Soil properties and enzyme activities in plots without and with rodent exclusion. Values are means ± SE, n = 24. Means in a row are not significantly different except for urease activity (P < 0.05)

effect of rodent exclusion on soil organic carbon content. Since evergreen broad-leaved forest are susceptible to extreme snow in the subtropical regions (Ge et al. 2015).

We found that rodent exclusion significantly decreased soil microbial biomass, which was inconsistent with our hypothesis and also with previous findings that increases in plant diversity increased soil microbial biomass (Jing et al. 2015; Lange et al. 2015). The significant difference in soil microbial biomass and community composition between plots with and without rodent exclusion has at least two possible explanations. First, increases in plant abundance and species richness in rodent exclusion plots may have increased plant uptake of nutrients and thereby increased the competition for nutrients experienced by soil microorganisms (Ullah et al. 2019; Wu et al. 2011). Second, plant seeds of canopy trees usually contain tannin, no matter the seed size is large or small (Wang et al. 2013; Yang et al. 2020), which may have suppressed soil microbial activity to a greater degree in plots with than without rodent exclusion.

Consistent with the decline in soil microbial biomass, soil basal respiration was significantly lower with than without rodent exclusion. According to multiple regression analysis, the major factor affecting soil basal respiration was the composition of the soil microbial community. Positive relationships between soil basal respiration and microbial biomass carbon were also reported in other ecosystems (Lange et al. 2015; Wardle and Zackrisson 2005). Although rodent exclusion reduced soil basal respiration, it did not significantly affect substrate-induced respiration, perhaps because of the high background level of carbon in the soil. A decrease in soil basal respiration has the potential to increase soil carbon sequestration over the long term. Another experiment at the same study site also found that net ecosystem CO₂ exchange and ecosystem respiration were strongly decreased by heavy snow in 2015 but then sharply increased in 2016 (Song et al. 2017a), which supported our results.

Based on our camera trap surveys (unpublished data), some other mammals have been occasionally detected (e.g., muntjacs and boars) although small rodents are the dominant floor animals in our study forest. Nevertheless, our enclosure treatment excluded all kinds of floor animals, and there faeces may potentially affect the soil properties. Furthermore, the enclosure may have little effects on light penetration, air flow, temperature, and moisture, because of the relatively large openings in the mesh. Scatter-hoarding rodents play an important role on seedling regeneration in our study forest via seed predation and seed dispersal (Lang and Wang 2016). As we
suggested earlier in the Discussion that heavy snowfall is likely to increase the percentage of seeds consumed by rodents, such that the effects of rodents on plant regeneration would differ depending on whether or not exclusion occurred after a heavy snowfall. In addition, the dominant herbivores in our study forest were insects (unpublished data of herbivory survey), so the effect of rodents on seedling damage can be ignored. Therefore, the effects of enclosure on seedling regeneration may mainly depend on seed predation and dispersal by rodents.

Conclusions
This study presented plant-rodent interactions after heavy snowfall in an old growth forest. We compared plots with and without rodent exclusion following a heavy snowfall in an old forest. There were three main ecological outputs. First, rodent exclusion enhanced plant regeneration (as indicated by increased plant species richness and abundance). Second, soil basal respiration was strongly decreased by rodent exclusion, which indicates that plant–rodent interactions indirectly affect soil carbon dynamics. Third, the main factor associated with the decrease in soil basal respiration and therefore with the potential for increased soil carbon sequestration in rodent-exclusion plots was the composition of the soil microbial community, which in turn was regulated by plants. The above conclusions and implications produced by this study can be important for sustainable forest management in face of extreme snow storm in future.
