Abstract
Background: Heart failure (HF) after kidney transplantation is a significant but understudied problem. Pretransplant dialysis modality could influence incident HF risk through differing cardiac stressors. However, whether pretransplant dialysis modality is associated with the development of posttransplant HF is unknown. Methods: We used the US Renal Data System to assemble a cohort of 27,701 patients who underwent their first kidney transplant in the USA between the years 2005 and 2012 and who had Medicare fee-for-service coverage for >6 months preceding their transplant date. Patients with any HF diagnosis prior to transplant were excluded. Detailed baseline patient characteristics and co-morbidities were abstracted. The outcome of interest was de novo posttransplant HF. Pretransplant dialysis modality was defined as the dialysis modality used at the time of transplant. We conducted time-to-event analyses using Cox regression. Death was treated as a competing risk in the study’s primary analysis. Graft failure was included as a time-varying covariate. Results: Among eligible patients, 81% were treated with hemodialysis prior to transplant, and hemodialysis patients were more likely to be male, had a shorter dialysis vintage, and had more diabetes and vascular disease diagnoses. When adjusted for all available demographic and clinical data, pretransplant treatment with hemodialysis (vs. peritoneal dialysis) was associated with a 19% increased risk in de novo posttransplant HF, with sub-distribution HR 1.19 (95% CI: 1.09–1.29). Conclusions: Our results suggest that choice of pretransplant dialysis modality may impact the development of posttransplant HF.

Introduction

For many patients with end-stage kidney disease (ESKD), kidney transplantation offers the best outcome in terms of survival and quality of life [1, 2]. However, survival of patients with a kidney transplant is still reduced compared to that of the general population, an effect attributable, at least in part, to an excess risk of cardiovascular disease in the kidney transplant population.
Heart failure (HF) following kidney transplant is a particularly important problem. Posttransplant HF is the most frequent cardiovascular cause for hospital admission in the 2 years following transplant and is associated with reduced patient and graft survival [4, 5].

Patients with ESKD are exposed to a myriad of both traditional and nontraditional risk factors for HF [6–12]. Chronic intermittent hemodialysis (vs. peritoneal dialysis) exposes patients to a number of unique cardiac stressors including (1) frequent and rapid intravascular volume shifts, (2) myocardial stunning, and (3) the presence of AV shunts that usually remain in situ after they receive a kidney transplant. We therefore hypothesized that those patients undergoing hemodialysis (vs. peritoneal dialysis) would be at higher risk for posttransplant HF. Herein, we formally examine the association between pretransplant dialysis modality and the incidence of de novo posttransplant HF using a large, population-based US ESKD registry.

Methods

Study Cohort

We used the US Renal Data System (USRDS) dataset to identify adult patients who underwent their first kidney transplant in the USA between January 1, 2005, and September 30, 2012. We required that patients have at least 6 months of Medicare Parts A and B coverage prior to their kidney transplant. Prior diagnoses of HF were identified using International Classification of Diseases, 9th revision (ICD-9), codes of 428.xx, 402.01, 402.11, 402.91, 404.01, 404.03, 404.11, 404.13, 404.91, and 404.93. We excluded patients with any inpatient or outpatient HF claims in up to 2 years prior to kidney transplant. We additionally excluded (1) patients for whom data on pretransplant dialysis modality were missing, (2) patients that received a simultaneous kidney-pancreas transplant, and (3) patients for whom there were no Medicare claims visible in the 2 years prior to transplant.

Exposure

The exposure of interest was the last pretransplant dialysis modality (hemodialysis vs. peritoneal dialysis) as reported in the USRDS treatment history files.

Outcome

The outcome was de novo posttransplant HF. HF was identified using ICD-9 claims. To ascertain de novo HF, we required either 1 posttransplant inpatient HF claim or 1 outpatient HF claim followed by another either inpatient or outpatient HF claim within 30 days of the first. For outpatient HF diagnosis, the date of the first outpatient claim was the date used for de novo HF. Patients were censored at the end of the study (September 30, 2015), loss of Medicare Parts A and B coverage, or at 3 years after transplant (as many patients lose Medicare coverage at this point).

Statistical Analysis

Baseline characteristics were tabulated for all patients as well as separately for the pretransplant hemodialysis and peritoneal dialysis groups. Continuous variables were presented as either means with standard deviations or medians with interquartile ranges where appropriate. Categorical variables were expressed as percentages. We presented cumulative incidence function plots to compare 3-year cumulative incidence of HF and death by pretransplant modality type.

We estimated unadjusted and incrementally adjusted sub-distribution or cause-specific hazard ratios for de novo posttransplant HF by pretransplant dialysis modality (with peritoneal dialysis being the reference). All models were stratified by the era of transplant; 2005–06, 2007–08, 2009–10, and 2011–12. Models 1–4 were incrementally adjusted as follows: model 1 – time-varying graft failure; model 2 – model 1 plus age at time of transplant, sex, race, BMI, cause of ESRD, dialysis vintage, and duration of last pretransplant dialysis modality; model 3 – model 2 plus comorbidities, health care utilization metrics (nursing home stay, number of hospital days, and number of non-nephrology clinic visits), and prior solid organ transplant status and; model 4 – model 3 plus transplant characteristics. The primary analysis treated death as a competing risk and generated sub-distribution hazard ratios using the Kaplan-Meier multiple imputation method [13, 14]. A secondary analysis treated death as a censoring event. Both analyses used extended Cox models. We tested for proportional hazards by looking at the correlation of the scaled Schoenfeld residuals with time and found no evidence that the log-hazard ratio changed with follow-up time for any of the covariates that were included in the model. The p value for the global test was 0.49. We additionally tested a number of pretransplant patient characteristics as effect modifiers of pretransplant dialysis modality (hemodialysis vs. peritoneal dialysis) on de novo posttransplant HF in the primary analysis. The pretransplant characteristics that were tested were (1) age at time of transplant, (2) race, (3) dialysis vintage, (4) dialysis modality
Dialysis Modality and Posttransplant Heart Failure

vintage, (5) BMI, (6) the presence of coronary artery disease, and (7) the presence of diabetes mellitus.

In our cohort of 27,701 patients, 6,842 (24.7%) had at least 1 variable missing. The variables most frequently missing were calculated panel-reactive antibody (15%) and cold ischemia time (8%). Data were assumed to be missing at random. Missing data were handled using multiple imputation by fully conditional specification as implemented in SAS, and 25 imputed datasets were obtained for the primary outcome. In addition to the exposure and all covariates included in the analysis model, the imputation model also included the event indicator and the Nelson-Aalen estimator of the cumulative marginal hazard. Imputation models were run separately for the main analysis (to calculate sub-distribution HR). Imputation models were stratified by treatment modality. Statistical analyses were performed using SAS software, version 9.4 (SAS Institute, Inc., Cary, NC, USA), R version 3.1.2, and Stata MP, version 13.1 (StataCorp, College Station, TX, USA).

Results

A total of 27,701 adults who underwent their first kidney transplant and satisfied all inclusion criteria were included in the study (Fig. 1). Of these, 81% of patients were treated with hemodialysis prior to transplant while the remaining 19% were treated with peritoneal dialysis for a median of 3.2 and 3.7 years, respectively. The baseline characteristics of the study cohort stratified by pretransplant dialysis modality are shown in Table 1. Patients treated with hemodialysis prior to transplant were more likely to be male, African American, had a shorter dialysis vintage, and had a greater burden of diabetes and vascular disease.

| PVD                       | 5,233 (18.9)    | 4,731 (21.1)    | 502 (9.4)      |
| Liver disease             | 4,496 (16.2)    | 3,834 (17.1)    | 662 (12.4)     |
| Tobacco use               | 2,397 (8.7)     | 2,010 (9.0)     | 387 (7.3)      |
| Arrhythmia                | 1,463 (5.3)     | 1,252 (5.6)     | 211 (4.0)      |
Over a mean follow-up of 2.33 years, 3,283 patients (11.9%) were diagnosed with de novo HF, with a median time from transplant surgery to a de novo HF diagnosis of 9.7 months (interquartile range, 2.13–22.03); among those previously treated with hemodialysis, 2,809 (12.6%) developed de novo HF compared with 8.8% of those previously treated with PD.

Pretransplant hemodialysis (vs. peritoneal dialysis) treatment was associated with an increased risk of post-transplant HF (Fig. 2; Table 2). The unadjusted and model 4-adjusted sub-distribution HRs for de novo HF for hemodialysis versus peritoneal dialysis were 1.36 (95% CI: 1.27, 1.46) and 1.19 (95% CI: 1.09–1.28), respectively.

Results were similar when death was treated as a censoring event. Complete results for both models that use death as a competing risk and death-censoring models are shown in Table 2.

There was a significant interaction identified for BMI ($p$ value for interaction = 0.03) and diabetes mellitus ($p$ value for interaction = 0.008), where higher BMI and the presence of pretransplant diabetes mellitus were synergistically associated with an increased risk of de novo posttransplant HF in those patients treated before transplant with hemodialysis (vs. peritoneal dialysis). More specifically, in patients with a pretransplant BMI of $\geq$30 kg/m², hemodialysis (vs. peritoneal dialysis) treatment
was associated with a 36% (95% CI: 13%–64%) increase in the sub-distribution hazard of de novo HF in those who were event free or died. However, there was no significant difference observed in the sub-distribution hazard of de novo HF in patients without diabetes mellitus treated with hemodialysis versus peritoneal dialysis. Full results for the interaction analysis are shown in Figure 3.

Table 2. Risk of de novo posttransplant heart failure in patients treated before transplant with hemodialysis versus peritoneal dialysis

| Models     | Sub-distribution HR (95% CI)* | Cause-specific HR (95% CI)* |
|------------|-------------------------------|----------------------------|
| Model 1    | 1.36 (1.27–1.46)              | 1.37 (1.28–1.46)            |
| Model 2    | 1.24 (1.14–1.34)              | 1.25 (1.15–1.34)            |
| Model 3    | 1.18 (1.09–1.28)              | 1.19 (1.09–1.29)            |
| Model 4    | 1.19 (1.09–1.28)              | 1.20 (1.10–1.29)            |

Model 1, calendar year and graft failure; model 2, model 1 + age at time of transplant, sex, race, BMI, cause of ESRD, and modality duration and dialysis vintage; model 3, model 2 + comorbidities, health care utilization metrics, and prior solid organ transplant status; model 4, model 3 + transplant characteristics. Graft failure was treated as a time-varying covariate. All models were stratified by incidence year categories (2005–2006, 2007–2008, 2009–2010, and 2011–2012). CI, confidence interval; HR, hazard ratio. *Sub-distribution hazard ratio treats death as a competing event; cause-specific hazard ratio treats death as a censoring event.

Discussion

In this study of US patients with ESKD on dialysis who received a first kidney-only transplant, we found that pretransplant treatment with hemodialysis (vs. peritoneal dialysis) was associated with de novo posttransplant HF. After adjustment for numerous potential confounders, those patients treated with hemodialysis before undergoing transplant had an almost 20% higher risk of being diagnosed with HF in the 3 years after transplant compared to those patients who were treated with peritoneal dialysis. The increased risk of posttransplant HF associated with receipt of pretransplant hemodialysis therapy was greater in those patients with a high BMI and in those with pre-existing diabetes mellitus.

Chronic cardiac volume and pressure overload may complicate both peritoneal dialysis and hemodialysis therapies and can result in the development of left ventricular hypertrophy, which is a precursor of both diastolic and systolic cardiac dysfunction. Both modalities also have distinct (modality specific) features that are relevant to the development of structural cardiac disease and warrant discussion.
Hemodialysis is associated with large, intermittent, and "unphysiological" volume shifts. Large interdialytic weight gains have been shown to be associated with the development of left ventricular hypertrophy while more frequent hemodialysis (compared to standard frequency) appears to protect against the development of left ventricular hypertrophy [15–17]. Hemodialysis-induced myocardial stunning/ischemia is a now well-described
phenomenon which also likely results in incremental myocardial injury [18]. The use of arteriovenous shunts for hemodialysis access results in an obligate increase in cardiac output and the development of left ventricular hypertrophy. In patients with high-flow arteriovenous fistulas, high output cardiac failure may sometimes ensue. Some (although not all) observational studies show that arteriovenous fistula ligation is associated with favorable left ventricular structural and functional changes [12, 19–21]; a randomized trial in 64 patients found that arteriovenous fistula ligation caused significant reductions in left ventricular mass and size [22].

Peritoneal dialysis which offers smooth and continuous volume removal should better mimic normal physiology. However, volume control with peritoneal dialysis may be imperfect [23, 24]. Peritoneal dialysis may also predispose to an unfavorable metabolic and inflammatory milieu which may contribute adversely to cardiac pathophysiology [25]. Sparse data comparing left ventricular hypertrophy prevalence in peritoneal dialysis versus hemodialysis patients yield conflicting results [26, 27]. In patients with existing HF and ESKD, peritoneal dialysis is often favored over hemodialysis as being potentially better hemodynamically tolerated; however, this practice is not supported by the results of a large (albeit retrospective and potentially confounded) study [28].

Our study has several strengths. Our cohort is large and from a relatively recent era. By using the USRDS and linked Medicare fee-for-service claims data, we are able to ascertain richly detailed patient demographic and clinical characteristics. However, as with all retrospective claims-based studies, residual confounding through either incorrectly or uncollected covariates is a possibility. We do not have access to cardiac investigations, dialysis prescriptions, medication history, or laboratory results including posttransplant glomerular filtration rate. We also do not have information regarding the type of pretransplant hemodialysis access.

Posttransplant HF is an important problem and is associated with reduced graft and patient survival [5]. Minimizing cardiac stress and injury should be an important focus of pretransplant management in patients with chronic kidney disease. Ideally, all patients with ESKD should undergo pre-emptive kidney transplant, which is associated with the best posttransplant outcomes [29, 30]. However, long deceased donor waiting times and insufficient numbers of living donors mean that pre-emptive kidney transplant is not an option for the majority of Americans with ESKD. Therefore, identifying modifiable dialysis-related risk factors for the development of posttransplant heart disease that may help to extend the lives of kidney transplant recipients is imperative. Our findings suggest that further study regarding the impact of pretransplant dialysis modality on posttransplant cardiac function is warranted.
