Efficient Representation of Large-Alphabet Probability Distributions

Aviv Adler, Member, IEEE, Jennifer Tang, Member, IEEE, and Yury Polyanskiy, Senior Member, IEEE

Abstract—A number of engineering and scientific problems require representing and manipulating probability distributions over large alphabets, which we may think of as long vectors of reals summing to 1. In some cases it is required to represent such a vector with only 6 bits per entry. A natural choice is to partition the interval \([0,1]\) into \(2^b\) uniform bins and quantize entries to each bin independently. We show that a minor modification of this procedure — applying an entrywise non-linear function (compander) \(f(x)\) prior to quantization — yields an extremely effective quantization method. For example, for \(b = 8\) (16) and \(10^2\)-sized alphabets, the quality of representation improves from a loss (under KL divergence) of 0.5(0.1) bits/entry to \(10^{-4}(10^{-9})\) bits/entry. Compared to floating point representations, our compander method improves the loss from \(10^{-1}(10^{-6})\) to \(10^{-4}(10^{-9})\) bits/entry. These numbers hold for both real-world data (word frequencies in books and DNA k-mer counts) and for synthetic randomly generated distributions. Theoretically, we analyze a minimax optimality criterion and show that the closed-form compander \(f(x) \propto \text{ArcSinh}(\sqrt{c_{K}}(K\log K)x)\) is (asymptotically as \(b \to \infty\)) optimal for quantizing probability distributions over a \(K\)-letter alphabet. Non-asymptotically, such a compander (substituting \(1/2\) for \(c_{K}\) for simplicity) has KL-quantization loss bounded by \(\leq 8 \cdot 2^{-2b} \log^2 K\). Interestingly, a similar minimax criterion for the quadratic loss on the hypercube shows optimality of the standard uniform quantizer. This suggests that the ArcSinh quantizer is as fundamental for KL-distortion as the uniform quantizer for quadratic distortion.

Index Terms—Quantization (signal), data compression.

I. COMPANDER BASICS AND DEFINITIONS

CONSIDER the problem of quantizing the probability simplex \(\Delta_{K-1} = \{x \in \mathbb{R}^K : x \geq 0, \sum_i x_i = 1\}\) of alphabet size \(K\), i.e., of finding a finite subset \(\mathcal{Z} \subseteq \Delta_{K-1}\) to represent the entire simplex. Each \(x \in \Delta_{K-1}\) is associated with some \(z = z(x) \in \mathcal{Z}\), and the objective is to find a set \(\mathcal{Z}\) and an assignment such that the difference between the values \(x \in \Delta_{K-1}\) and their representations \(z \in \mathcal{Z}\) is minimized; while this can be made arbitrarily small by making \(\mathcal{Z}\) arbitrarily large, the goal is to do this efficiently for any given fixed size \(|\mathcal{Z}| = M\). Since \(x, z \in \Delta_{K-1}\), they both represent probability distributions over a size-\(K\) alphabet. Hence, a natural way to measure the quality of the quantization is to use the KL (Kullback-Leibler) divergence \(D_{KL}(x||z)\), which corresponds to the excess code length for lossless compression and is commonly used as a way to compare probability distributions. (Note that we want to minimize the KL divergence.)

While one can consider how to best represent the vector \(x\) as a whole, in this paper we consider only scalar quantization methods in which each element \(x_i\) of \(x\) is handled separately, since we showed in [1] that for Dirichlet priors on the simplex, methods using scalar quantization perform nearly as well as optimal vector quantization. Scalar quantization is also typically simpler and faster to use, and can be parallelized easily. Our scalar quantizer is based on companders (portmanteau of ‘compressor’ and ‘expander’), a simple, powerful and flexible technique first explored by Bennett in 1948 [2] in which the value \(x_i\) is passed through a nonlinear function \(f\) before being uniformly quantized. We discuss the background in greater depth in Section III.

In what follows, log is always base-e unless otherwise specified. We denote \([N] := \{1, \ldots, N\}\).

A. Encoding

Companders require two things: a monotonically increasing function \(f : [0,1] \to [0,1]\) (we denote the set of such functions as \(\mathcal{F}\)) and an integer \(N\) representing the number of quantization levels, or granularity. To simplify the problem and algorithm, we use the same \(f\) for each element of the vector \(x = (x_1, \ldots, x_K) \in \Delta_{K-1}\) (see Remark 1). To quantize \(x \in [0,1]\), the compander computes \(f(x)\) and applies a uniform quantizer with \(N\) levels, i.e., encoding \(x\) to \(n_X(x) \in [N]\) if \(f(x) \in \left(\frac{n-1}{N}, \frac{n}{N}\right]\); this is equivalent to \(n_X(x) = \lceil f(x)N \rceil\). This encoding partitions \([0,1]\) into bins \(I^{(n)}\):

\[x \in I^{(n)} = f^{-1}\left(\left(\frac{n-1}{N}, \frac{n}{N}\right]\right) \iff n_X(x) = n\]

where \(f^{-1}\) denotes the preimage under \(f\).

2We require increasing functions as a convention, so larger \(x_i\) map to larger values in \([N]\). Note that \(f\) does not need to be strictly increasing; if \(f\) is flat over interval \(I \subseteq [0,1]\) then all \(x_i \in I\) will always be encoded by the same value. This is useful if no \(x_i\) in \(I\) ever occurs, i.e., \(I\) has zero probability mass under the prior.
As an example, consider the function \( f(x) = x^4 \). Varying \( s \) gives a natural class of functions from \([0, 1]\) to \([0, 1]\), which we call the class of power companders. If we select \( s = 1/2 \) and \( N = 4 \), then the 4 bins created by this encoding are

\[
I^{(1)} = (0, 1/16], I^{(2)} = (1/16, 1/4], I^{(3)} = (1/4, 9/16], I^{(4)} = (9/16, 1].
\]

**B. Decoding**

To decode \( n \in [N] \), we pick some \( \gamma(n) \in I^{(n)} \) to represent all \( x \in I^{(n)}; \) for a given \( x \) (at granularity \( N \)), its representation is denoted \( \gamma(x) = \gamma(n(x)) \). This is generally either the midpoint or, if \( x \) is drawn randomly from a known prior\(^3\), the centroid (the mean within bin \( I^{(n)} \)). The midpoint and centroid of \( I^{(n)} \) are defined, respectively, as

\[
\tilde{\gamma}(n) = \frac{1}{2}(f^{-1}\left(\frac{n-1}{N}\right) + f^{-1}\left(\frac{n}{N}\right)),
\]

\[
\gamma(n) = E_{X \sim P}[X | X \in I^{(n)}].
\]

We will discuss this in greater detail in Section I-D.

Handling each element of \( x \) separately means the decoded values may not sum to 1, so we normalize the vector after decoding. Thus, if \( x \) is the input,

\[
z(x) = \frac{y(x)}{\sum_{j=1}^{K} y(x)}
\]

and the vector \( z = z(x) = (z_1(x), \ldots, z_K(x)) \in \Delta_{K-1} \) is the output of the compander. This notation reflects the fact that each entry of the normalized reconstruction depends on all of \( x \) due to the normalization step. We refer to \( y = y(x) = (y(x_1), \ldots, y(x_K)) \) as the raw reconstruction of \( x \), and \( z \) as the normalized reconstruction. If the raw reconstruction uses centroid decoding, we likewise denote it using \( \tilde{y} = \tilde{y}(x) = (\tilde{y}(x_1), \ldots, \tilde{y}(x_K)) \). For brevity we may sometimes drop the \( x \) input in the notation, e.g., \( z := z(x) \); if \( x \) is random we will sometimes denote its quantization as \( Z := z(X) \).

Thus, any \( x \in \Delta_{K-1} \) requires \( K\log_2 N \) bits to store; to encode and decode, only \( f \) and \( N \) need to be stored (as well as the prior if using centroid decoding). Another major advantage is that a single \( f \) can work well over many or all choices of \( N \), making the design more flexible.

**C. KL Divergence Loss**

The loss incurred by representing \( x \) as \( z := z(x) \) is the KL divergence

\[
D_{KL}(x||z) = \sum_{i=1}^{K} x_i \log \frac{x_i}{z_i}.
\]

Although this loss function has some unusual properties (for instance \( D_{KL}(x||z) \neq D_{KL}(z||x) \) and it does not obey the triangle inequality) it measures the amount of ‘mis-representation’ created by representing the probability vector \( x \) by another probability vector \( z \), and is hence a natural quantity to minimize. In particular, it represents the excess code length created by trying to encode the output of \( x \) using a code built for \( z \), as well as having connections to hypothesis testing (a natural setting in which the ‘difference’ between probability distributions is studied).

**D. Distributions From a Prior**

Much of our work concerns the case where \( x \in \Delta_{K-1} \) is drawn from some prior \( P_x \) (to be commonly denoted as simply \( P \)). Using a single \( f \) for each entry means we can WLOG assume that \( P \) is symmetric over the alphabet, i.e., for any permutation \( \sigma \), if \( X \sim P \) then \( \sigma(X) \sim P \) as well. This is because for any prior \( P \) over \( \Delta_{K-1} \), there is a symmetric prior \( P^* \) such that

\[
E_{X \sim P}[D_{KL}(X||z(X))] = E_{X \sim P^*}[D_{KL}(X'||z'(X'))]
\]

for all \( f \), where \( z(X) \) is the result of quantizing (to any number of levels) with \( f \) as the compander. To get \( X' \sim P^* \) and a uniformly random permutation \( \sigma \), and let \( X' = \sigma(X) \).

We denote the set of symmetric priors as \( P^*_K \). Note that a key property of symmetric priors is that their marginal distributions are the same across all entries, and hence we can speak of \( P \in P^*_K \) having a single marginal \( p \).

**Remark 1:** In principle, given a nonsymmetric prior \( P_x \) over \( \Delta_{K-1} \) with marginals \( p_1, \ldots, p_K \), we could quantize each letter’s value with a different compander \( f_1, \ldots, f_K \), giving more accuracy than using a single \( f \) (at the cost of higher complexity). However, the symmetrization of \( P_x \) over the letters (by permuting the indices randomly after generating \( X \sim P_x \)) yields a prior in \( P^*_K \) on which any single \( f \) will have the same (overall) performance and cannot be improved on by using varying \( f_i \). Thus, considering symmetric \( P_x \) suffices to derive our minimax compander.

While the random probability vector comes from a prior \( P \in P^*_K \), our analysis will rely on decomposing the loss so we can deal with one letter at a time. Hence, we work with the marginals \( p \) of \( P \) (which are identical since \( P \) is symmetric), which we refer to as single-letter distributions and are probability distributions over \([0, 1]\).

We let \( \mathcal{P} \) denote the class of probability distributions over \([0, 1]\) that are absolutely continuous with respect to the Lebesgue measure. We denote elements of \( \mathcal{P} \) by their probability density functions (PDF), e.g., \( p \in \mathcal{P} \); the cumulative distribution function (CDF) associated with \( p \) is denoted \( F_p \) and satisfies \( F_p(x) = p(x) \) and \( F_p(x) = \int_0^x p(t) \, dt \) (since \( F_p \) is monotonic, its derivative exists almost everywhere). Note that while \( p \in \mathcal{P} \) does not have to be continuous, its CDF \( F_p \) must be absolutely continuous. Following common terminology [3], we refer to such probability distributions as continuous.

Let \( \mathcal{P}_{1/K} = \{ p \in \mathcal{P} : E_{X \sim P}[X] = 1/K \} \). Note that \( P \in P^*_K \) implies its marginals \( p \) are in \( \mathcal{P}_{1/K} \).

**E. Expected Loss and Preliminary Results**

For \( P \in P^*_K \), \( f \in \mathcal{F} \) and granularity \( N \), we define the expected loss:

\[
\mathcal{L}_K(P, f, N) = E_{X \sim P}[D_{KL}(X||z(X))].
\]

This is the value we want to minimize over \( f \).

**Remark 2:** While \( X \) and \( z(X) \) are random, they are also probability vectors. The KL divergence \( D_{KL}(X||z(X)) \) is the
divergence between \( X \) and \( z(X) \) themselves, not the prior distributions over \( \Delta_{K-1} \) they are drawn from.

Note that \( L_K(P, f, N) \) can almost be decomposed into a sum of \( K \) separate expected values, except the normalization step (1) depends on the random vector \( X \) as a whole. Hence, we define the raw loss:

\[
\tilde{L}_K(p, f, N) = \mathbb{E}_{X-p}\left[ \sum_{i=1}^{K} X_i \log(X_i/\tilde{y}(X_i)) \right].
\]

(3)

We also define for \( p \in \mathcal{P} \), the single-letter loss as

\[
\tilde{L}(p, f, N) = \mathbb{E}_{X-p}\left[ X \log(X/\tilde{y}(X)) \right].
\]

(4)

The raw loss is useful because it bounds the (normalized) expected loss and is decomposable into single-letter losses. Note that both raw and single-letter loss are defined with centroid decoding.

Proposition 1: For \( P \in \mathcal{P}_K^\Delta \) with marginals \( p \),

\[
L_K(P, f, N) \leq \tilde{L}_K(P, f, N) = K \tilde{L}(p, f, N).
\]

Proof: Separating out the normalization term gives

\[
L(P, f, N) = \mathbb{E}_{X-p}[D_{KL}(X||z(X))]
= \tilde{L}_K(P, f, N) + \mathbb{E}_{X-p}\left[ \log \left( \sum_{i=1}^{K} \tilde{y}(X_i) \right) \right].
\]

Since \( \mathbb{E}[^{(\mid)}] = \mathbb{E}[^{\circ}] \) for all \( i \), \( \sum_{i=1}^{K} \mathbb{E}[\tilde{y}(X_i)] =\sum_{i=1}^{K} \mathbb{E}[X_i] = 1 \). Because log is concave, by Jensen’s Inequality

\[
\mathbb{E}_{X-p}\left[ \log \left( \sum_{i=1}^{K} \tilde{y}(X_i) \right) \right] \leq \log \left( \mathbb{E} \left[ \sum_{i=1}^{K} \tilde{y}(X_i) \right] \right)
= \log(1) = 0
\]

and we are done.

To derive our results about worst-case priors (for instance, Theorem 1), we will also be interested in \( \tilde{L}(p, f, N) \) even when \( p \) is not known to be a marginal of some \( P \in \mathcal{P}_K^\Delta \).

Remark 3: Though one can define raw and single-letter loss without centroid decoding (replacing \( \tilde{y} \) in (3) or (4) with another decoding method \( \hat{y} \)), this removes much of their usefulness. This is because the resulting expected loss can be dominated by the difference between \( \mathbb{E}[X] \) and \( \mathbb{E}[\tilde{y}(X)] \), potentially even making it negative; specifically, the Taylor expansion of \( X \log(X/\tilde{y}(X)) \) has \( X - \tilde{y}(X) \) in its first term, which can have negative expectation.

While this can make the expected ‘raw loss’ negative under general decoding, it cannot be exploited to make the (normalized) expected loss negative because the normalization step \( z(X) = \tilde{y}(X)/\sum_i \tilde{y}(X_i) \) cancels out the problematic term. Centroid decoding avoids this problem by ensuring \( \mathbb{E}[X] = \mathbb{E}[\tilde{y}(X)] \), removing the issue.

As we will show, when \( N \) is large these values are roughly proportional to \( N^{-2} \) (for well-chosen \( f \)) and so we define the asymptotic single-letter loss:

\[
\tilde{L}(p, f) = \lim_{N \to \infty} N^2 \tilde{L}(p, f, N).
\]

(5)

We similarly define \( \tilde{L}_K(p, f) \) and \( L_K(p, f) \). While the limit in (5) does not necessarily exist for every \( p, f \), we will show that one can ensure it exists by choosing an appropriate \( f \) (which works against any \( p \in \mathcal{P} \)), and cannot gain much by not doing so.

II. RESULTS

We demonstrate, theoretically and experimentally, the efficacy of companding for quantizing probability distributions with KL divergence loss.

A. Theoretical Results

While we will occasionally give intuition for how the results here are derived, our primary concern in this section is to fully state the results and to build a clear framework for discussing them.

Our main results concern the formulation and evaluation of a minimax compander \( f_K^* \) for alphabet size \( K \), which satisfies

\[
f_K^* = \arg\min_{f} \sup_{p \in \mathcal{P}_{1/K}} \tilde{L}(p, f).
\]

(6)

We require \( p \in \mathcal{P}_{1/K} \) because if \( p \in \mathcal{P}_K^\Delta \) and is symmetric, its marginals are in \( \mathcal{P}_{1/K} \).

The natural counterpart of the minimax compander \( f_K^* \) is the maximin density \( p_K^* \) in \( \mathcal{P}_{1/K} \), satisfying

\[
p_K^* = \arg\max_{p \in \mathcal{P}_{1/K}} \inf_{f \in \mathcal{F}} \tilde{L}(p, f).
\]

(7)

We call (6) and (7), respectively, the minimax condition and the maximin condition.

In the same way that the minimax compander gives the best performance guarantee against an unknown single-letter prior \( p \in \mathcal{P}_{1/K} \) (asymptotic as \( N \to \infty \)), the maximin density is the most difficult prior to quantize effectively as \( N \to \infty \). Since they are highly related, we will define them together:

Proposition 2: For alphabet size \( K > 4 \), there is a unique \( c_K \in \left[ \frac{1}{4}, \frac{3}{4} \right] \) such that if \( a_K = (4/(c_K K \log K + 1))^{1/3} \) and \( b_K = 4/a_K - a_K \), then the following density is in \( \mathcal{P}_{1/K} \):

\[
p_K^*(x) = (a_K x^{1/3} + b_K x^{4/3})^{-3/2}.
\]

(8)

Furthermore, \( \lim_{K \to \infty} c_K = 1/2 \).

Note that this is both a result and a definition: we show that \( a_K, b_K, c_K \) exist which make the definition of \( p_K^* \) possible. With the constant \( c_K \), we define the minimax compander:

Definition 1: Given the constant \( c_K \) as shown to exist in Proposition 2, the minimax compander is the function \( f_K^* : [0, 1] \to [0, 1] \) where

\[
f_K^*(x) = \frac{\text{ArcSinh}\left(\sqrt{c_K \log K} x\right)}{\text{ArcSinh}\left(\sqrt{c_K \log K} \right)}.
\]

The approximate minimax compander \( f_K^{**} \) is

\[
f_K^{**}(x) = \frac{\text{ArcSinh}\left(\sqrt{(1/2) \log K} x\right)}{\text{ArcSinh}\left(\sqrt{(1/2) \log K} \right)}.
\]

(9)

Remark 4: While \( f_K^* \) and \( f_K^{**} \) might seem complex, \( \text{ArcSinh}(\sqrt{w}) = \log(w + \sqrt{w + 1}) \) so they are relatively simple functions to work with.

We will show that \( f^*_K, p^*_K \) as defined above satisfy their respective conditions (6) and (7).

**Theorem 1:** The minimax compander \( f^*_K \) and maximin single-letter density \( p^*_K \) satisfy

\[
\sup_{p \in \mathcal{P}_{1/K}} \bar{L}(p, f^*_K) = \inf_{f \in \mathcal{F}} \sup_{p \in \mathcal{P}_{1/K}} \bar{L}(p, f) \tag{10}
\]

\[
= \sup_{p \in \mathcal{P}_{1/K}} \inf_{f \in \mathcal{F}} \tilde{L}(p, f) = \inf_{f \in \mathcal{F}} \tilde{L}(p^*_K, f) \tag{11}
\]

which is equal to \( \tilde{L}(p^*_K, f^*_K) \) and satisfies

\[
\tilde{L}(p^*_K, f^*_K) = \frac{1}{24} (1 + o(1)) K^{-1} \log^2 K. \tag{12}
\]

Since any symmetric \( p \in \mathcal{P}^\Delta_K \) has marginals \( p \in \mathcal{P}_{1/K} \), this (with Proposition 1) implies an important corollary for the normalized KL-divergence loss incurred by using the minimax compander:

**Corollary 1:** For any prior \( p \in \mathcal{P}^\Delta_K \),

\[
L_K(p, f^*_K) \leq \tilde{L}_K(p, f^*_K) = \frac{1}{24} (1 + o(1)) \log^2 K.
\]

However, the set of symmetric \( p \in \mathcal{P}^\Delta_K \) does not correspond exactly with \( p \in \mathcal{P}_{1/K} \): while any symmetric \( p \in \mathcal{P}^\Delta_K \) has marginals \( p \in \mathcal{P}_{1/K} \), it is not true that any given \( p \in \mathcal{P}_{1/K} \) has a corresponding symmetric prior \( P \in \mathcal{P}^\Delta_K \). Thus, it is natural to ask: can the minimax compander’s performance be improved by somehow taking these ‘shape’ constraints into account? The answer is ‘not by more than a factor of 2’.

**Proposition 3:** There is a prior \( p^* \in \mathcal{P}^\Delta_K \) such that for any \( P \in \mathcal{P}^\Delta_K \),

\[
\inf_{f \in \mathcal{F}} \tilde{L}_K(P, f) \geq \frac{K - 1}{2K} \tilde{L}_K(P, f^*_K).
\]

While the minimax compander satisfies the minimax condition (6), it requires working with the constant \( c_k \), which, while bounded, is tricky to compute or use exactly. Hence, in practice we advocate using the approximate minimax compander (9), which yields very similar asymptotic performance without needing to know \( c_k \):

**Proposition 4:** Suppose that \( K \) is sufficiently large so that \( c_k \in \left[ \frac{1}{2(1 + \epsilon)}, \frac{1 + \epsilon}{2} \right] \). Then for any \( p \in \mathcal{P} \),

\[
\tilde{L}(p, f^*_K) \leq (1 + \epsilon) \tilde{L}(p, f^*_K).
\]

Before we show how we get Theorem 1, we make the following points:

**Remark 5:** If we use the uniform quantizer instead of minimax there exists a \( P \in \mathcal{P}^\Delta_K \) where

\[
\mathbb{E}_{X \sim p} [D_{KL}(X || Z)] = \Theta \left( K^2 N^{-2} \log N \right).
\]

This is done by using marginal density \( p \) uniform on \([0, 2/K] \). To get a prior \( P \in \mathcal{P}^\Delta_K \) with these marginals, if \( K \) is even, we can pair up indices so that \( x_{2j-1} = 2K - x_{2j} \) for all \( j = 1, \ldots, K/2 \) (for odd \( K \), set \( x_K = 1/K \)) and then symmetrize by permuting the indices. See Appendix F in the supplementary material for more details.

The dependence on \( N \) is worse than \( N^{-2} \) resulting in \( \tilde{L}(p, f) = \infty \). This shows theoretical suboptimality of the uniform quantizer. Note also that the quadratic dependence on \( K \) is significantly worse than the \( \log^2 K \) dependence achieved by the minimax compander.

Incidentally, other single-letter priors such as \( p(x) = (1 - \alpha)x^{-\alpha} \) where \( \alpha = \frac{K-2}{K-1} \) can achieve worse dependence on \( N \) (specifically, \( N^{-(2-\alpha)} \) for this prior). However, the example above achieves a bad dependence on both \( N \) and \( K \) simultaneously, showing that in all regimes of \( K, N \) the uniform quantizer is vulnerable to bad priors.

**Remark 6:** Instead of the KL divergence loss on the simplex, we can do a similar analysis to find the minimax compander for \( L^2 \) loss on the unit hypercube. The solution is given by the identity function \( f(x) = x \) corresponding to the standard (non-companded) uniform quantization. (See Section VI.)

To show Theorem 1 we formulate and show a number of intermediate results which are also of significant interest for a theoretical understanding of companding under KL divergence, in particular studying the asymptotic behavior of \( \tilde{L}(p, f, N) \) as \( N \to \infty \). We define:

**Definition 2:** For \( p \in \mathcal{P} \) and \( f \in \mathcal{F} \), let

\[
L^*(p, f) = \frac{1}{24} \int_0^1 p(x)f'(x)^{-1} x^{-1} dx = \mathbb{E}_{X \sim p} \left[ \frac{1}{24} f'(X)^{-1} X^{-1} \right]. \tag{13}
\]

For full rigor, we also need to define a set of ‘well-behaved’ companders:

**Definition 3:** Let \( \mathcal{F}^+ \subseteq \mathcal{F} \) be the set of \( f \) such that for each \( f \) there exist constants \( c > 0 \) and \( \alpha \in [0, 1/2] \) for which \( f(x) - cx^\alpha \) is still monotonically increasing.

Then the following describes the asymptotic single-letter loss of compander \( f \) on prior \( p \) (with centroid decoding):

**Theorem 2:** For any \( p \in \mathcal{P} \) and \( f \in \mathcal{F} \),

\[
\lim_{N \to \infty} N^2 \tilde{L}(p, f, N) \geq L^*(p, f). \tag{14}
\]

Furthermore, if \( f \in \mathcal{F}^+ \) then an exact result holds:

\[
\tilde{L}(p, f) = L^*(p, f) < \infty. \tag{15}
\]

The intuition behind the formula for \( L^*(p, f) \) is that as \( N \to \infty \), the density \( p \) becomes roughly uniform within each bin \( t^n \). Additionally, the bin containing a given \( x \in [0, 1] \) will have width \( t^n \approx N^{-1} f'(x)^{-1} \). Then, letting \( \text{unif}_{t^n} \) be the uniform distribution over \( t^n \) and \( \tilde{y}_n \approx x \) be the midpoint of \( t^n \) (which is also the centroid under the uniform distribution), we apply the approximation

\[
\mathbb{E}_{X \sim \text{unif}_{t^n}} \left[ X \log(X/\tilde{y}_n) \right] \approx \frac{1}{24} \frac{1}{t^n} \tilde{y}_n^{-1} \approx \frac{1}{24} N^{-2} f'(x)^{-2} x^{-1}.
\]

Averaging over \( X \sim p \) and multiplying by \( N^2 \) then gives (13). One wrinkle is that we need to use the Dominated Convergence Theorem to get the exact result (15), but we cannot necessarily apply it for all \( f \in \mathcal{F} \); instead, we can apply it for all \( f \in \mathcal{F}^+ \) and outside of \( \mathcal{F}^+ \) we get (14) using Fatou’s Lemma.
While limiting ourselves to \( f \in \mathcal{F}^+ \) might seem like a serious restriction, it does not lose anything essential because \( \mathcal{F}^+ \) is ‘dense’ within \( \mathcal{F} \) in the following way:

**Proposition 5:** For any \( f \in \mathcal{F} \) and \( \delta \in (0, 1] \),

\[
f_\delta(x) = (1 - \delta)f(x) + \delta x^{1/2}
\]

satisfies \( f_\delta \in \mathcal{F}^+ \) and

\[
\lim_{\delta \to 0} \tilde{L}(p, f_\delta) = \lim_{\delta \to 0} L^*(p, f_\delta) = L^*(p, f).
\]

**Remark 7:** It is important to note that strictly speaking the limit represented by \( \tilde{L}(p, f) \) may not always exist if \( f \notin \mathcal{F}^+ \). However, (i) one can always guarantee that it exists by selecting \( f \in \mathcal{F}^+ \); (ii) by (14), it is impossible to use \( f \) outside \( \mathcal{F}^+ \) to get asymptotic performance better than \( L^*(p, f) \); and (iii) by Proposition 5, given \( f \) outside \( \mathcal{F}^+ \), one can get a compander in \( \mathcal{F}^+ \) with arbitrarily close (or better) performance to \( f \) by using \( f_\delta(x) = (1 - \delta)f(x) + \delta x^{1/2} \) for \( \delta \) close to 0. This suggests that considering only \( f \in \mathcal{F}^+ \) is sufficient since there is no real way to benefit by using \( f \notin \mathcal{F}^+ \).

Additionally, both \( f^*_k \) and \( f^{**}_k \) are in \( \mathcal{F}^+ \). Thus, in Theorem 1, although the limit might not exist for certain \( f \in \mathcal{F} \), \( p \in \mathcal{P}_1/K \), the minimax compander still performs better since it has less loss than even the lim inf of the loss of other comparand.

Given Theorem 2, it’s natural to ask: for a given \( p \in \mathcal{P} \), what compander \( f \) minimizes \( L^*(p, f) \)? This yields the following by calculus of variations:

**Theorem 3:** The best loss against source \( p \in \mathcal{P} \) is

\[
\inf_{f \in \mathcal{F}} L(p, f) = \min_{f \in \mathcal{F}} L^*(p, f) = \frac{1}{24} \left( \int_0^1 (p(x)x^{-1})^{1/3} \, dx \right)^3
\]  

where the optimal compander against \( p \) is

\[
f^*_p(x) = \arg\min_{f \in \mathcal{F}} L^*(p, f) = \left[ \int_0^1 (p(t)t^{-1})^{1/3} \, dt \right]^{1/3}.
\]

(satisfying \( f^*_p(x) \propto (p(x)x^{-1})^{1/3} \)).

Note that \( f^*_p \) may not be in \( \mathcal{F}^+ \) (for instance, if \( p \) assigns zero probability mass to an interval \( I \subseteq [0, 1] \), then \( f^*_p \) will be constant over \( I \)). However, this can be corrected by taking a convex combination with \( x^{1/2} \) as described in Proposition 5.

The expression (17) represents in a sense how hard \( p \in \mathcal{P} \) is to quantize with a compander, and the maximin density \( p^*_K \) is the density in \( \mathcal{P}_1/K \) which maximizes it.\(^5\) In turn, the minimax compander \( f^*_k \) is the optimal compander against \( p^*_K \), i.e.,

\[
f^*_k = f^*_p |_{p = p^*_K}.
\]

So far we considered quantization of a random probability vector with a known prior. We next consider the case where the quantization guarantee is given pointwise, i.e., we cover \( \Delta_{K-1} \) with a finite number of KL divergence balls of fixed radius. That note that since the prior is unknown, only the midpoint decoder can be used.

\(^5\) The maximizing density over all \( p \in \mathcal{P} \) happens to be \( p(x) = \frac{1}{2} x^{-1/2} \); however, \( E_{x \sim p}[X] = 1/3 \) so it cannot be the marginal of any symmetric \( p \in \mathcal{P}^+ \) when \( K > 3 \).

**Theorem 4 (Divergence Covering):** On alphabet size \( K > 4 \) and \( N \geq 8 \log(2\sqrt{K} \log K + 1) \), the minimax and approximate minimax comparand with midpoint decoding achieve worst-case loss over \( \Delta_{K-1} \) of

\[
\max_{x \in \Delta_{K-1}} D_{KL}(x\|z) \leq (1 + \text{err}(K,N))N^{-2} \log^2 K
\]

where \( \text{err}(K) \) is an error term satisfying

\[
\text{err}(K) \leq 18 \log \log K \leq 7 \text{ when } K > 4.
\]

Note that the non-asymptotic worst-case bound matches (up to a constant factor) the known-prior asymptotic result (12). We remark that condition on \( N \) is mild: for example, if \( N = 256 \) (i.e., we are representing the probability vector with 8 bits per entry), then \( N > 8 \log(2\sqrt{K} \log K + 1) \) for all \( K \leq 2.6 \times 10^5 \).

**Remark 8:** When \( b \) is the number of bits used to quantize each value in the probability vector, using the approximate minimax compander yields a worst-case loss on the order of \( 2^{-3b} \log^2 K \). In [5] we prove bounds on the optimal loss under arbitrary (vector) quantization of probability vectors and show that this loss is sandwiched between \( 2^{-2b} \log^2 K \) (Theorem 2) and \( 2^{-2b} \log^2 K \) (Theorem 4). Thus, the entrywise comparand in this work are quite competitive.

We also consider the natural family of power comparand \( f(x) = x^s \), both in terms of average asymptotic raw loss and worst-case non-asymptotic normalized loss. By definition, \( f(x) \in \mathcal{F}^+ \) and hence \( \tilde{L}(p, f) \) is well-defined and Theorem 2 applies.

**Theorem 5:** The power compander \( f(x) = x^s \) with exponent \( s \in (0, 1/2] \) has asymptotic loss

\[
\sup_{p \in \mathcal{P}_1/K} \tilde{L}(p, f) = \frac{1}{24} s^{-2} K^{2s-1}.
\]

For \( K > 7 \), (19) is minimized by setting \( s = \frac{1}{\log K} \) (when \( K \leq 7 \), \( \frac{1}{\log K} > 1/2 \) and \( f(x) = x^{1/2} \) achieves

\[
\sup_{p \in \mathcal{P}_1/K} \tilde{L}(p, f) = \frac{e^2}{24} \frac{1}{K} \log^2 K
\]

and

\[
\sup_{p \in \mathcal{P}_1/K} \tilde{L}(p, f) = \frac{e^2}{24} \log^2 K.
\]

Additionally, when \( s = \frac{1}{\log K} \), it achieves the following worst-case bound with midpoint decoding for \( K > 7 \) and \( N > \frac{3}{2} \log K \):

\[
\max_{x \in \Delta_{K-1}} D_{KL}(x\|z) \leq (1 + \text{err}(K,N)) \frac{e^2}{2} N^{-2} \log^2 K
\]

where \( \text{err}(K,N) \leq \frac{e^2}{2} \). Note in particular that when \( N \geq e \log K \), we have \( \text{err}(K,N) \leq 1 \), giving a bound of \( \max_{x \in \Delta_{K-1}} D_{KL}(x\|z) \leq e^2 N^{-2} \log^2 K \).

We can think of \( s = \frac{1}{\log K} \) as a ‘minimax’ among the class of power comparand. This result shows \( f(x) = x^{\frac{1}{\log K}} \) has performance within a constant factor of the minimax compander, and hence might be a good alternative.
B. Experimental Results

We compare the performance of five quantizers, with granularities $N = 2^{8}$ and $N = 2^{16}$, on three types of datasets of various alphabet sizes:

- Random synthetic distributions drawn from the uniform prior over the simplex: We draw and take the average over 1000 random samples for our results.
- Frequency of words in books: These frequencies are computed from text available on the Natural Language Toolkit (NLTK) libraries for Python. For each text, we get tokens (single words or punctuation) from each text and simply count the occurrence of each token.
- Frequency of $k$-mers in DNA: For a given sequence of DNA, the set of $k$-mers are the set of length $k$ substrings which appear in the sequence. We use the human genome as the source for our DNA sequences. Parts of the sequence marked as repeats are removed.

Our quantizers are:

- **Approximate Minimax Compander**: As given by equation (9). Using the approximate minimax compander is much simpler than the minimax compander since the constant $c_K$ does not need to be computed.
- **Truncation**: Uniform quantization (equivalent to $f(x) = x$), which truncates the least significant bits. This is the natural way of quantizing values in $[0, 1]$.
- **Float and bfloat16**: For 8-bit encodings ($N = 2^{8}$), we use a floating point implementation which allocates 4 bits to the exponent and 4 bits to the mantissa. For 16-bit encodings ($N = 2^{16}$), we use bfloat16, a standard which is commonly used in machine learning [6].
- **Exponential Density Interval (EDI)**: This is the quantization method we used in an achievability proof in [1]. It is designed for the uniform prior over the simplex.
- **Power Compander**: Recall that the compander is $f(x) = x^s$. We optimize $s$ and find that $s = \frac{1}{\log K}$ asymptotically minimizes KL divergence, and also gives close to the best performance among power companders empirically. To see the effects of different powers $s$ on the performance of the power compander, see Figure 1.

Because a well-defined prior does not always exist for these datasets (and for simplicity) we use midpoint decoding for all the companders. When a probability value of exactly 0 appears, we do not use companding and instead quantize the value to 0, i.e., the value 0 has its own bin.

Our main experimental results are given in Figure 2, showing the KL divergence between the empirical distribution $x$ and its quantized version $z$ versus alphabet size $K$. The approximate minimax compander performs well against all sources. For truncation, the KL divergence increases with $K$ and is generally fairly large. The EDI quantizer works well for the synthetic uniform prior (as it should), but for real-world datasets like word frequency in books, it performs badly (sometimes even worse than truncation). The loss of the power compander is similar to the minimax compander (only worse by a constant factor), as predicted by Theorem 5.

The experiments show that the approximate minimax compander achieves low loss on the entire ensemble of data (even for relatively small granularity, such as $N = 256$) and outperforms both truncation and floating-point implementations on the same number of bits. Additionally, its closed-form expression (and entrywise application) makes it simple to implement and computationally inexpensive, so it can be easily added to existing systems to lower storage requirements at little or no cost to fidelity.

C. Paper Organization

We provide background and discuss previous work on quantizers in Section III. We prove Theorem 2 in Section IV (though proofs of some lemmas and propositions leading up to it are given in Appendix A in the supplementary material). Proposition 5 is proved in Appendix B in the supplementary material. In Section V, we optimize over (13) to get the maximin single-letter distribution (showing part of Proposition 2 with other parts left to Appendix D-A in the supplementary material) and the minimax compander, thus
showing Theorem 1, 3, Corollary 1 and Proposition 3 (leaving Theorem 4 for Appendix D-B in the supplementary material). We prove Theorem 4 and the worst-case part of Theorem 5 in Appendix E in the supplementary material. Other parts of Theorem 5 are discussed in Appendix C-B in the supplementary material. In Section VI we discuss companders for losses other than KL divergence. Finally, in Section VII we discuss a connection of our problem to the problem of information distillation with proofs given in Appendix G in the supplementary material.

In Section VI we discuss companders for losses other than KL divergence. Finally, in Section VII we discuss a connection of our problem to the problem of information distillation with proofs given in Appendix G in the supplementary material.

III. BACKGROUND

Companders (also spelled “compandors”) were introduced by Bennett in 1948 [2] as a way to quantize speech signals, where it is advantageous to give finer quantization levels to points and their associated centers. Theoretical aspects of this problem was discussed in Appendix D-B in the supplementary material and some other parts of the paper are in Appendix E in the supplementary material. In Section VI we discuss companders for losses other than KL divergence. Finally, in Section VII we discuss a connection of our problem to the problem of information distillation with proofs given in Appendix G in the supplementary material.

A variant of the classic problem of prediction with log-loss is an equivalent formulation to quantizing the simplex with KL loss: let \( x \in \Delta_{K-1} \) and \( A \sim x \) (in the alphabet \([K] \)); we want to predict \( A \) by positing a distribution \( z \in \Delta_{K-1} \), and our loss is \(-\log z_A \). In the standard version, the problem is to pick the best \( z \) given limited information about \( x \); however, if we know \( x \) but are required to express \( z \) using only \( \log_2 N \) bits, it is equivalent to quantizing the simplex with KL divergence loss.

IV. ASYMPTOTIC SINGLE-LETTER LOSS

In this section we give the proof of Theorem 2 (though the proofs of some lemmas must be sketched). We use the following notation:

Given an interval \( I \) we define \( \tilde{y}_I \) to be its midpoint and \( r_I \) to be its width, so that by definition

\[
I = \left[ \frac{\tilde{y}_I - r_I/2}{\tilde{y}_I + r_I/2} \right].
\]

Note that if \( I \subseteq [0, 1] \) then \( r_I \leq 2\tilde{y}_I \).

Given probability distribution \( p \) and interval \( I \), we denote the following: \( p|_I \) is restricted to \( I \); \( \pi_{p,I} := \mathbb{P}_{X \sim p}[X \in I] \) is the probability mass of \( I \); and the centroid of \( I \) under \( p \) is

\[
\tilde{y}_{p,I} := \mathbb{E}_{X \sim p | X \in I}[X] = \mathbb{E}_{X \sim p}[X | X \in I].
\]

If they are undefined because \( \mathbb{P}_{X \sim p}[X \in I] = 0 \) then by convention \( p|_I \) is uniform on \( I \) and \( \tilde{y}_{p,I} = \tilde{y}_I \).

When \( I = I^{(n)} \) is a bin of the compander, we can replace it with \( (n) \) in the notation, i.e., \( \tilde{y}_I = \tilde{y}_{(n)} \) (so the midpoint of the bin containing \( x \) at granularity \( N \) is denoted \( \tilde{y}_{(n)}(x) \)) and the width of the bin is \( r_{(n)}(x) \). When \( I \) and/or \( p \) are fixed, we sometimes drop them from the notation, i.e., \( \tilde{y}_I \) or even just \( \tilde{y} \) to denote the centroid of \( I \) under \( p \).

A. The Local Loss Function

One key to the proof is the following perspective: instead of considering \( X \sim p \) directly, we (equivalently) first select bin \( I^{(n)} \) with probability \( \pi_{p,(n)} \), and then select \( X \sim p|_{(n)} \). The expected loss can then be considered within bin \( I^{(n)} \). This makes it useful to define:

**Definition 4:** Given probability measure \( p \) and interval \( I \), the single-interval loss of \( I \) under \( p \) is

\[
\ell_{p,I} = \mathbb{E}_{X \sim p|_I}[X \log(X/\tilde{y}_{p,I})].
\]

As before, if \( p \) and/or \( I \) is fixed and clear, we can drop it from the notation (and if \( I = I^{(n)} \) is a bin, we can denote the local loss as \( \ell_{p,(n)} \). This can be interpreted as follows: if we quantize all \( x \in I \) to the centroid \( \tilde{y}_I \), then \( \ell_{p,I} \) is the expected loss of \( X \sim p \) conditioned on \( X \in I \). Thus the values of \( \ell_{p,(n)} \) can be used as an alternate means of computing the single-letter loss:

\[
\tilde{L}(p,f,N) = \mathbb{E}_{X \sim p}[X \log(X/\tilde{y}(X))]
\]

\[
= \sum_{n=1}^{N} \pi_{p,(n)} \mathbb{E}_{X \sim p|_{(n)}}[X \log(X/\tilde{y}_{p,(n)})]
\]

\[
= \sum_{n=1}^{N} \pi_{p,(n)} \ell_{p,(n)} = \int_{[0,1]} \ell_{p,(n)}(x) \, dp(n).
\]

Authorized licensed use limited to: MIT Libraries. Downloaded on December 01,2023 at 04:43:10 UTC from IEEE Xplore. Restrictions apply.
Thus the normalized single-letter loss (whose limit is the asymptotic single-letter loss (5)) is
\[ N^2 \tilde{L}(p, f, N) = \int_{[0,1]} N^2 \ell_{p, (\eta_N(x))} \, dp. \]
For single-letter density \( p \) and compander \( f \), we define the local loss function at granularity \( N \):
\[ g_N(x) = N^2 \ell_{p, (\eta_N(x))}. \tag{21} \]
We also define the asymptotic local loss function:
\[ g(x) = \frac{1}{24} f'(x)^2 x^{-1}. \]

Theorem 2 is therefore equivalent to:
\[
\liminf_{N \to \infty} \int g_N \, dp \geq \int g \, dp \quad \forall p \in \mathcal{P}, f \in \mathcal{F} \tag{22}
\]
and
\[
\lim_{N \to \infty} \int g_N \, dp = \int g \, dp \quad \forall p \in \mathcal{P}, f \in \mathcal{F}^\dagger. \tag{23}
\]
To prove (22) and (23), we show:

**Proposition 6**: For all \( p \in \mathcal{P}, f \in \mathcal{F} \), if \( X \sim p \) then
\[ \lim_{N \to \infty} g_N(X) = g(X) \]
almost surely.

**Proposition 7**: Let \( f \in \mathcal{F}^\dagger \) be a compander and \( c > 0 \) and \( \alpha \in (0, 1] \) such that \( f(x) - cx^\alpha \) is monotonically increasing. Letting \( g_N \) be the local loss functions as in (21) and
\[ h(x) = \left( 2^{2/\alpha} + \alpha^2 2^{1/\alpha - 2} \right) (\alpha c)^{-2} x^{1 - 2\alpha} + c^{-1/\alpha} 2^{2/\alpha - 2}, \]
then \( g_N(x) \leq h(x) \) for all \( x, N \). Additionally, if \( \alpha \leq 1/2 \) then
\[ \int_{[0,1]} h \, dp < \infty. \]
The lower bound (22) then follows immediately from Proposition 6 and Fatou's Lemma; and when \( f \in \mathcal{F}^\dagger \), by Proposition 7 there is some \( h \) which is integrable over \( p \) and dominates all \( g_N \), thus showing (23) by the Dominated Convergence Theorem.

To prove Proposition 6, we use the following:
- For any \( x \) at which \( f \) is differentiable, when \( N \) is large, the width of the interval \( x \) falls in is 
  \[ r_{(\eta_N(x))} \approx N^{-1} f'(x)^{-1}. \]
- For any \( x \) at which \( F_p \) is differentiable, \( p|_I \) will be approximately uniform over any sufficiently small \( I \) containing \( x \).
- For a sufficiently small interval \( I \) containing \( x \) and such that \( p|_I \) is approximately uniform, 
  \[ \ell_{p, I} \approx \frac{1}{24} f'(x)^- x^{-1}. \]
Putting these together, we get that if \( F_p \) and \( f \) are both differentiable at \( x \) then when \( N \) is large,
\[ g_N(x) \approx N^2 \ell_{p, (\eta_N(x))} \approx N^2 \frac{1}{24} r_{(\eta_N(x))}^2 x^{-1} \approx \frac{1}{24} f'(x)^2 x^{-1} = g(x) \]
as we wanted. We formally state each of these steps in Appendix A-B in the supplementary material and combine them to prove Proposition 6 in Appendix A-C in the supplementary material.

The proof of Proposition 7 is given in Appendix A-D in the supplementary material, along with its own set of definitions and lemmas needed to show it.

**V. MINIMAX COMPANDER**

Theorem 2 showed that for \( f \in \mathcal{F}^\dagger \), the asymptotic single-letter loss is equivalent to
\[ \tilde{L}(p, f) = \frac{1}{24} \int_0^1 p(x) f'(x)^2 x^{-1} \, dx. \]
Using this, we can analyze what is the ‘best’ compander \( f \) we can choose and what is the ‘worst’ single-letter density \( p \) in order to show Theorem 1 and 3 and their related results.

**A. Optimizing the Compander**

We show Theorem 3, which follows from Theorem 2 by finding \( f \in \mathcal{F} \) which minimizes \( L^\dagger(p, f) \). This is achieved by optimizing over \( f^\dagger \); we will also use some concepts from Proposition 5 to connect it back to \( \min_{p \in \mathcal{P}} \tilde{L}(p, f) \) when the resulting \( f \) is not in \( \mathcal{F}^\dagger \). Since \( f : [0,1] \to [0,1] \) is monotonic, we use constraints \( f^\dagger(x) \geq 0 \) and \( f^\dagger_0 f^\dagger(x) = 1 \). We solve the following:

\[
\begin{align*}
\text{minimize} & \quad L^\dagger(p, f) = \frac{1}{24} \int_0^1 p(x) f'(x)^2 x^{-1} \, dx \\
\text{subject to} & \quad \int_0^1 f^\dagger(x) \, dx = 1 \\
& \quad f^\dagger(x) \geq 0 \quad \forall x \in [0,1].
\end{align*}
\]

The function \( L^\dagger(p, f) \) is convex in \( f^\dagger \), and thus first order conditions show optimality. Let \( \lambda(x) \) satisfy \( \int_0^1 \lambda(x) \, dx = 0 \). If \( f^\dagger(x) \propto (p(x)x^{-1})^{1/3} \), we derive:
\[
\begin{align*}
\frac{d}{dt} \frac{1}{24} \int_0^1 p(x) \left( f'(x) + t \lambda(x) \right)^2 x^{-1} \, dx \\
&= -\frac{1}{24} \int_0^1 p(x) x^{-1} f'(x) \lambda(x) \, dx \\
&= -\frac{1}{12} \int_0^1 p(x) x^{-1} f'(x)^3 \lambda(x) \, dx \quad \text{(at } t = 0) \\
&= -\frac{1}{12} \int_0^1 p(x) x^{-1} f'(x)^3 \lambda(x) \, dx \\
&= 6 \int_0^1 \lambda(x) \, dx = 0.
\end{align*}
\]
Thus, such \( f \) satisfies the first-order optimality condition under the constraint \( \int f^\dagger(x) \, dx = 1 \). This gives \( f^\dagger_0(x) \propto (p(x)x^{-1})^{1/3} \) and \( f(0) = 0 \) and \( f(1) = 1 \), from which (17) and (18) follow. If \( f_p \in \mathcal{F}^\dagger \), then \( f_p = \arg \min_{f \in \mathcal{F}} \tilde{L}(p, f) \), and for any other \( f \in \mathcal{F} \),
\[ \tilde{L}(p, f_p) = L^\dagger(p, f_p) \leq L^\dagger(p, f) \leq \liminf_{N \to \infty} N^2 \tilde{L}(p, f, N). \]
If \( f_p \notin \mathcal{F}^\dagger \), for any \( \delta > 0 \) define \( f_{p,\delta} = (1 - \delta)f_p + \delta t^{1/2} \) (as in (16)). Then \( f_{p,\delta} - \delta t^{1/2} = (1 - \delta)f_p \) is monotonically increasing so \( f_{p,\delta} \in \mathcal{F}^\dagger \), so Theorem 2 applies to \( f_{p,\delta} \); additionally, \( f_{p,\delta} - (1 - \delta)f_p = \delta t^{1/2} \) is monotonically increasing as well so \( f_{p,\delta} \geq (1 - \delta)f_p \). Hence, plugging into the \( L^1 \) formula gives:

\[
\tilde{L}(p, f_{p,\delta}) = L^1(p, f_{p,\delta}) \leq L^1(p, f_p)(1 - \delta)^{-2}.
\]

Taking \( \delta \to 0 \) (and since \( \mathcal{F}^\dagger \subseteq \mathcal{F} \)) shows that

\[
\tilde{L}(p, f_p) = \inf_{f \in \mathcal{F}^\dagger} \tilde{L}(p, f),
\]

finishing the proof of Theorem 3.

Remark 10: Since we know the corresponding single-letter source \( p \) for a Dirichlet prior, using this \( p \) with Theorem 3 gives us the optimal compander for Dirichlet priors on any alphabet size. This gives us a better quantization method than EDI which was discussed in Section II-B. This optimal compander for Dirichlet priors is called the beta compander and its details are given in Appendix C-A in the supplementary material.

B. The Minimax Companders and Approximations

To prove Theorem 1 and Corollary 1, we first consider what density \( p \) maximizes equation (17):

\[
\frac{1}{24} \left( \int_0^1 \left( p(x)x^{-1} \right)^{1/3} dx \right)^3
\]

i.e., is most difficult to quantize with a compander. Using calculus of variations to maximize

\[
\int_0^1 \left( p(x)x^{-1} \right)^{1/3} dx
\]

(which of course maximizes (17)) subject to \( p(x) \geq 0 \) and \( \int_0^1 p(x) dx = 1 \), we find that maximizer is \( p(x) = \frac{1}{2} x^{-1/2} \). However, while interesting, this is only for a single letter; and because \( \mathbb{E}[X] = 1/3 \) under this distribution, it is clearly impossible to construct a prior over \( \Delta_{K-1} \) whose output vector must sum to 1 with this marginal (unless \( K = 3 \)).

Hence, we add an expected value constraint to the problem of maximizing (25), giving:

\[
\text{maximize } \int_0^1 \left( p(x)x^{-1} \right)^{1/3} dx \\
\text{subject to } \int_0^1 p(x) dx = 1; \\
\int_0^1 p(x)x dx = \frac{1}{K}; \\
\text{and } p(x) \geq 0 \text{ for all } x.
\]

We can solve this again using variational methods (we are maximizing a concave function so we only need to satisfy first-order optimality conditions). A function \( p(x) > 0 \) is optimal if, for any \( \lambda(x) \) where

\[
\int_0^1 \lambda(x) dx = 0 \text{ and } \int_0^1 \lambda(x)x dx = 0
\]

the following holds:

\[
\frac{d}{dt} \int_0^1 x^{-1/3}(p(x) + t\lambda(x))^{1/3} dx = 0.
\]

We have by the same logic as before:

\[
\frac{d}{dt} \int_0^1 x^{-1/3}(p(x) + t\lambda(x))^{1/3} dx \\
= \frac{1}{3} \int_0^1 x^{-1/3}(p(x) + t\lambda(x))^{-2/3}\lambda(x) dx \\
= \frac{1}{3} \int_0^1 x^{-1/3}p(x)^{-2/3}\lambda(x) dx \text{ (at } t = 0). \tag{28}
\]

Thus, if we can arrange things so that there are constants \( a_K, b_K \) such that

\[
x^{-1/3}p(x)^{-2/3} = a_K + b_K x
\]

this ensures (28) equals zero. In that case,

\[
x^{-1/3}p(x)^{-2/3} = a_K + b_K x \\
\iff p(x)^{-2/3} = a_K x^{1/3} + b_K x^{4/3} \\
\iff p(x) = (a_K x^{1/3} + b_K x^{4/3})^{-3/2}. \tag{29}
\]

This is the maximin density \( p_K^{\star} \) from Proposition 2 (8), where \( a_K, b_K \) are set to meet the constraints (26) and (27). Exact formulas for \( a_K, b_K \) are difficult to find; we give more details on after the next step.

We want to determine the optimal compander for the maximin density (29). We know from (24) that we need to first compute

\[
\phi(x) = \frac{\int_0^x w^{-1/3}(a_K w^{1/3} + b_K w^{4/3})^{-1/2} dw}{2\text{ArcSinh}\left(\sqrt{\frac{b_K}{a_K}}\right)}. \tag{30}
\]

The best compander \( f(x) \) is proportional to (30) and is exactly given by \( f(x) = \phi(x)/\phi(1) \). The resulting compander, which we call the minimax compander, is

\[
f(x) = \frac{\text{ArcSinh}\left(\sqrt{\frac{b_K}{a_K}}\right)}{\text{ArcSinh}\left(\sqrt{\frac{b_K}{a_K}}\right)}. \tag{31}
\]

Given the form of \( f(x) \), it is natural to determine an expression for the ratio \( b_K/a_K \). We can parameterize both \( a_K \) and \( b_K \) by \( b_K/a_K \) and then examine how \( b_K/a_K \) behaves as a function of \( K \). The constraints on \( a_K \) and \( b_K \) give that

\[
a_K = 4^{1/3}(b_K/a_K + 1)^{-1/3} \\
b_K = 4a_K^2 - a_K.
\]

The ratio \( b_K/a_K \) grows approximately as \( K \log K \). Hence, we choose to parameterize

\[
b_K/a_K = c_K K \log K.
\]

To satisfy the constraints, we get \( 0.25 < c_K < 0.75 \) so long as \( K > 24 \) (see Appendix D-A in the supplementary material for details), and Lemma 11 in Appendix D-A2 in the supplementary material shows that \( c_K \to 1/2 \) as \( K \to \infty \). Combining these gives Proposition 2.
We can then express $a_K$, $b_K$ in terms of $c_K$:

$$a_K = 4^{1/3}(c_K K \log K + 1)^{-1/3}$$
$$b_K = 4a_K^2 - a_K$$

$$= 4^{1/3}(c_K K \log K + 1)^{2/3} - 4^{1/3}(c_K K \log K + 1)^{-1/3}$$
$$= 4^{1/3}(c_K K \log K)^{2/3}(1 + o(1)).$$

(32)

When $K$ is large, the second term in (32) is negligible compared to the first. Thus, plugging into (31) we get the minimax compander, and we can show that the pair $(f^+_K, a_K)$ is optimal against the maximin density $p^+$. For all $p \in \mathcal{P}_{1/K}$, $L^1 (f^+_K, a_K)$ is the optimal loss.

To compute the loss of the minimax compander, we can use (17) to get

$$L^1 (p^+_K, f^+_K) = \frac{1}{24} \left( \frac{2 \text{ArcSinh}(\sqrt{c_K K \log K})}{\sqrt{b_K}} \right)^3.$$ 

Substituting we get

$$L^1 (p^+_K, f^+_K) = \frac{1}{24} \left( \frac{2 \text{ArcSinh}(\sqrt{c_K K \log K})}{\sqrt{b_K}} \right)^3.$$ 

The minimax compander minimizes the maximum (raw) loss against all densities in $P_{1/K}$, while the approximate minimax compander performs very similarly but is more applicable since it can be used without computing $c_K$.

To compute the loss of the minimax compander, we can use (17) to get

$$L^1 (p^+_K, f^+_K) = \frac{1}{24} \left( \frac{2 \text{ArcSinh}(\sqrt{c_K K \log K})}{\sqrt{b_K}} \right)^3.$$

The minimax compander minimizes the maximum (raw) loss against all densities in $P_{1/K}$, while the approximate minimax compander performs very similarly but is more applicable since it can be used without computing $c_K$.
[b_{i-1}, b_i] and thus for any permutation \( \sigma \),
\[
\sum_{i=1}^{K} b_{i-1} \leq \sum_{i=1}^{K} X_{\sigma^{-1}(i)} \leq \sum_{i=1}^{K} b_i = \left( \sum_{i=1}^{K} b_{i-1} \right) + b_K - b_0 \leq \left( \sum_{i=1}^{K} b_{i-1} \right) + 1 \leq 2
\]
as \( \sum_i b_{i-1} \leq \sum_i E[X_{\sigma^{-1}(i)}] = KE_{X-p}[X] = 1. \)

Lemma 1 shows a joint distribution of \( W_1, \ldots, W_{K-1} \) such that \( W_i \sim p_K^x \) for all \( i \) and \( \sum_{i=1}^{K-1} W_i \leq 2 \) (guaranteed) exists. Then, if \( X_i = W_i/2 \) for all \( i \in [K-1] \), we have \( \sum_{i=1}^{K-1} X_i \leq 1. \)
Then setting \( X_K = 1 - \sum_{i=1}^{K-1} X_i \geq 0 \) ensures that \( X_1, \ldots, X_K \) is a probability vector. Denoting this prior \( P_{\text{hard}}^x \) and letting \( p_{K}^{x*}(x) = 2p_K^x(2x) \) (so \( W_i \sim p_K^x \Rightarrow X_i \sim p_{K}^{x*} \)) we get that
\[
\inf_{f \in \mathcal{F}} \tilde{L}_K(P_{\text{hard}}^x.f) \geq (K - 1) \inf_{f \in \mathcal{F}} \tilde{L}(p_{K}^{x*}.f) = (K - 1) \frac{1}{2} L^2(p_{K}^{x*}.f_k) \geq \frac{1}{2} \frac{K - 1}{K} \sup_{p \in P_K} \tilde{L}_K(P, p_k^x). \tag{34}
\]
The last inequality holds because \( p_{K}^{x*} \) is the maximum density (under expectation constraints). To make \( P_{\text{hard}}^x \) symmetric, we permute the letter indices randomly without affecting the raw loss; thus we get Corollary 1. To get (35) from (34), we have
\[
\inf_{f \in \mathcal{F}} \tilde{L}(2p_{K}^{x*}(2x), f) = \frac{1}{24} \left( \int_0^1 \left( 2p_{K}^{x*}(2x) \frac{1}{3} dx \right)^3 \right) \leq \frac{1}{24} \left( \int_0^1 \left( 2p_{K}^{x*}(u) \frac{1}{3} \frac{1}{2} dx \right)^3 \right) = \frac{1}{24} L^2(p_{K}^{x*}.f_s).
\]
This shows Proposition 3. In Figure 3, we validate the distribution \( P_{\text{hard}}^x \) by showing the performance of each compander when quantizing random distributions drawn from \( P_{\text{hard}}^x \). For the minimax compander, the KL divergence loss on the worst-case prior looks to be within a constant of that for the other datasets.

**VI. Companding Other Metrics and Spaces**

While our primary focus has been KL divergence over the simplex, for context we compare our results to what the same compander analysis would give for other loss functions like squared Euclidean distance (\( L_2^2 \)) and absolute distance (\( L_1 \) or TV distance). For a vector \( x \) and its representation \( z \) let
\[
L_2^2(x, z) = \sum_i (x_i - z_i)^2 \quad L_1(x, z) = \sum_i |x_i - z_i|.
\]

For squared Euclidean distance, asymptotic loss was already given by (20) in [2], and scales as \( N^{-2} \). It turns out that the maximin single-letter distribution over a bounded interval is the uniform distribution. Thus, the minimax compander for \( L_2^2 \) is simply the identity function, i.e., uniform quantization is the maximin for quantizing a hypercube in high-dimensional space under \( L_2^2 \) loss. (For unbounded spaces, \( L_2^2 \) loss does not scale with \( N^{-2} \).)

If we add the expected value constraint to the \( L_2^2 \) compander optimization problem, we can derive the best square distance compander for \( L_2^2 \) in the hypercube \( [0 \leq x_j \leq 1 \text{ for all } j] \). For alphabet size \( K \), we get that the minimax compander for \( L_2^2 \) is given by
\[
f_{L_2^2,K}(x) = \sqrt{1 + K(K - 2)x_1 - 1} \quad \frac{1}{K - 2}
\]
and the total \( L_2^2 \) loss for probability vector \( x \) and its quantization \( z \) has the relation
\[
\lim_{N \to \infty} N^2 L_2^2(x, z) \leq \frac{1}{3}.
\]

For \( L_1 \), unlike KL divergence and \( L_2^2 \), the loss scales as \( 1/N \). Like \( L_2^2 \), the minimax single-letter compander for \( L_1 \) loss in the hypercube \( [0 \leq x_j \leq 1 \text{ for all } j] \) is the identity function, i.e., uniform quantization. In general, the derivative of the optimal compander for single-letter density \( p(x) \) has the form
\[
f'_{L_1,K}(x) \propto \sqrt{p(x)}.
\]

On the probability simplex for alphabet size \( K \), the worst case prior \( p(x) \) has the form
\[
p(x) = (\alpha_K x + \beta_K)^{-2}
\]
where \( \alpha_K, \beta_K \) are constants scaling to allow \( f_{[0,1]} dp = 1 \) (i.e., \( p \) is a valid probability density) and \( \int_{[0,1]} x dp = 1/K \) (i.e., \( \mathbb{E}_X p[X] = 1/K \) so \( K \) copies of it are expected to sum to 1).

Thus, the minimax compander on the simplex for \( L_1 \) loss (and letting \( \gamma_K = \alpha_K / \beta_K \)) satisfies
\[
f'_{L_1,K}(x) \propto (\alpha_K x + \beta_K)^{-1} \quad \Rightarrow \quad f_{L_1,K}(x) \propto \log((\alpha_K / \beta_K)x + 1)
\]

since \( f_{L_1,K}(x) \) has to be scaled to go from 0 to 1.

The asymptotic \( L_1 \) loss for probability vector \( x \) and its quantization \( z \) is bounded by
\[
\lim_{N \to \infty} N L_1(x, z) = O(\log K).
\]
| Loss | Space   | Optimal Compannder                                      | Asymptotic Upper Bound |
|------|---------|--------------------------------------------------------|------------------------|
| KL   | Simplex | $f_K(x) = \frac{\text{ArcSinh}(\sqrt{e_{2K}(K \log K)} x)}{\text{ArcSinh}(\sqrt{e_{2K} K \log K})}$ | $N^{-2} \log^2 K$     |
| $L^2_2$ | Simplex | $f_{L^2_2,K}(x) = \frac{\sqrt{1+K(K-2)x} - x}{K-2}$ | $N^{-2} K$            |
| $L^2_2$ | Hypercube | $f_{L^2_2,K}(x) = x$ (uniform quantizer) | $N^{-2} K$            |
| $L_1$ (TV) | Simplex | $f_{L_1,K}(x) = \frac{\log(\gamma x+1)}{\log(\gamma+1)}$ | $N^{-1} \log K$       |
| $L_1$ (TV) | Hypercube | $f_{L_1}(x) = x$ (uniform quantizer) | $N^{-1} K$            |

Fig. 4. Summary of results for various losses and spaces. Asymptotic Upper Bound is an upper bound on how we expect the loss of the optimal compander to scale with $N$ and $K$ (constant terms are neglected).

VII. CONNECTION TO INFORMATION DISTILLATION

It turns out that the general problem of quantizing the simplex under the average KL divergence loss, as defined in (2), is equivalent to recently introduced problem of information distillation. Information distillation has a number of applications, including in constructing polar codes [21], [22]. In this section we establish this equivalence and also demonstrate how the compander-based solutions to the KL-quantization can lead to rather simple and efficient information distillers.

A. Information Distillation

In the information distillation problem we have two random variables $A \in \mathcal{A}$ and $B \in \mathcal{B}$, where $|\mathcal{A}| = K$ (and $\mathcal{B}$ can be finite or infinite) under joint distribution $P_{A,B}$ with marginals $P_A, P_B$. The goal is, given some finite $M < |\mathcal{B}|$, to find an information distiller (which we will also refer to as a distiller), which is a (deterministic) function $h: \mathcal{B} \to [M]$, which minimizes the information loss

$$I(A; B) - I(A; h(B))$$

associated with quantizing $B \to h(B)$. The interpretation here is that $B$ is a (high-dimensional) noisy observation of some important random variable $A$ and we want to record observation $B$, but only have $\log_2 M$ bits to do so. Optimal $h$ minimizes the additive loss entailed by this quantization of $B$.

To quantify the amount of loss incurred by this quantization, we use the degrading cost [21], [22]

$$DC(K, M) = \sup_{P_{A,B}} \inf_h I(A; B) - I(A; h(B))$$

Note that in supremizing over $P_{A,B}$ there is no restriction on $B$, only on $|\mathcal{A}|$ and the size of the range of $h$. It has been shown in [22] that there is a $P_{A,B}$ such that

$$\inf_h I(A; B) - I(A; h(B)) = \Omega\left(M^{-2/(K-1)}\right)$$

giving a lower bound to $DC(K, M)$. For an upper bound, [23] showed that if $2K < M < |\mathcal{B}|$, then

$$DC(K, M) = O\left(M^{-2/(K-1)}\right).$$

Specifically, $DC(K, M) \leq v(K) M^{-2/(K-1)}$ where $v(K) \approx 16\pi e K^2$ for large $K$. While [21] focused on multiplicative loss, their work also implied an improved bound on the additive loss as well; namely, for all $K \geq 2$ and $M^{1/(K-1)} \geq 4$, we have

$$DC(K, M) \leq 1268(K-1)M^{-2/(K-1)}.$$

B. Info Distillation Upper Bounds Via Companders

Using our KL divergence quantization bounds, we will show an upper bound to $DC(K, M)$ which improves on (36) for $K$ which are not too small and for $M$ which are not exceptionally large. First, we establish the relation between the two problems:

**Proposition 8**: For every $P_{A,B}$ define a random variable $X \in \Delta_{K-1}$ by setting $X_a = P(A = a | B)$. Then, for every information distiller $h : \mathcal{B} \to [M]$ there is a vector quantizer $z : \Delta_{K-1} \to \Delta_{K-1}$ with range of cardinality $M$ such that

$$I(A; B) - I(A; h(B)) \geq \mathbb{E}[D_{KL}(X||Z(X))].$$

Conversely, for any vector quantizer $z$ there exists a distiller $h$ such that

$$I(A; B) - I(A; h(B)) \leq \mathbb{E}[D_{KL}(X||Z(X))].$$

The inequalities in Proposition 8 can be replaced by equalities if the distiller $h$ and the quantizer $z$ avoid certain trivial inefficiencies. If they do so, there is a clean ‘equivalent’ quantizer $z$ for any distiller $h$, and vice versa, which preserves the expected loss. This equivalence and Proposition 8 are shown in Appendix G in the supplementary material.

Thus, we can use KL quantizers to bound the degrading cost above (see Appendix G in the supplementary material for details):

$$DC(K, M) = \sup_{P_{A,B}} \inf_h I(A; B) - I(A; h(B))$$

$$= \sup_{P_{A,B}} \inf_h \mathbb{E}_{X \sim P}[D_{KL}(X||Z)]$$

$$\leq \inf_h \mathbb{E}_{X \sim P}[D_{KL}(X||Z)].$$

We then use the approximate minimax compander results to give an upper bound to (38). This yields:

**Proposition 9**: For any $K \geq 5$ and $M^{1/K} > [8 \log(2\sqrt{K \log K} + 1)]$

$$DC(K, M) \leq \left(1 + 18 \frac{\log \log K}{\log K}\right) M^{-2/(K-1)}.$$

**Proof**: Consider the right-hand side of (37). The compander-based quantizer from Theorem 4 gives a guaranteed bound on $D(X||Z(X))$ (and $M = N^K$ substituted), which also holds in expectation. $\blacksquare$

**Remark 12**: Similarly, an upper bound on the divergence covering problem [5, Th. 2] implies

$$DC(K, M) \leq 800(\log K)M^{-2/(K-1)}.$$
we have a provable relationship between the metric entropy and distortion measures that satisfy the triangle inequality, though, see [14].

ACKNOWLEDGMENT

The authors would like to thank Anthony Philippakis for his guidance on the DNA k-mer experiments.
