ABSTRACT

Background: Myelodysplastic syndromes (MDS) are a diverse group of clonal hematopoietic stem cell malignancies that primarily affect the elderly. Although the incidence of MDS in western countries has been well investigated, little is known about the incidence in Asian populations.

Methods: To identify the incidence of MDS in Japan, we used population-based registry data from 1993 to 2008. The data represented 33.1% of the Japanese population. A total of 7995 patients were reported to the registry with newly diagnosed MDS during the study period.

Results: Median age at diagnosis was 76 years. Incidence sharply increased with age, particularly in those aged over 70 years. The most recent crude incidence rate of MDS was 3.8 (95% CI 3.6–4.1) cases per 100,000 for men and 2.4 (95% CI 2.2–2.6) cases per 100,000 for women in 2008. Age-adjusted incidences of MDS in 2008, standardized by the world standard population, were 1.6 and 0.8 cases per 100,000 for men and women, respectively, while incidences standardized by the 1985 Japanese population were 2.5 and 1.2 cases per 100,000 for men and women, respectively.

Conclusions: Our study reveals that some elderly patients suffer from MDS in Japan, but the incidence is lower than in Western countries. In current clinical practice, many elderly MDS patients are treated with supportive therapy based on an incomplete diagnosis, suggesting that the incidence estimated in this study might still be substantially underestimated. Accurate evaluation of the health impact of MDS requires evaluation of the mortality of the disease, continued surveillance, and improvement in the quality of cancer registry data.

Key words: myelodysplastic syndrome; MDS; incidence; epidemiology; Asia

INTRODUCTION

Myelodysplastic syndromes (MDS) are a diverse group of clonal hematopoietic stem cell malignancies in the elderly that present with persistent bone marrow failure and peripheral blood cytopenias. Approximately 30% of patients progress to acute myeloid leukemia, which is always fatal in the elderly.¹,² Population-based registry data in the United States (U.S.) and Europe indicate an incidence of MDS in western countries of around 2 to 4 cases per 100,000 person-years with male predominance.³,⁴ The descriptive epidemiology of MDS has been well investigated in western countries³–⁸ but not in Asian populations, partly because of the scarcity of population-based registry data for MDS in Asia. A U.S. study showed that incidence differed by race,³ indicating that reference data in Asians based on population-based data would be of interest.

Several studies have reported the characteristics of MDS in Asian populations.⁹–¹² Matsuda et al reported differences in the characteristics of MDS between patients in Japan and Germany, in which they found that the patients’ median age of 57 years in Japan was significantly younger than the median age of 71 years in German patients.¹¹ Median age at diagnosis of other reports from Asia was 60 and 62 years, which also suggest younger age of MDS in an Asian population.⁹,¹² However, these studies were conducted using a case-series design, and their data were not population-based. Patients in case series rarely represent general patient populations, and their data cannot be used to estimate incidence in a population.

Here, we evaluated the incidence and trends in MDS in Japan using population-based registry data in Japan.

METHODS

We used population-based cancer registry data from the Monitoring of Cancer Incidence in Japan (MCIJ) project, which was started in 2007 as a national project that aimed to collect and unite the cancer registry data of each of Japan’s prefectures using a standardized protocol. MCIJ data have previously been used to estimate annual cancer incidences in Japan. For the quality control, prefectures that reported death certificate notices (DCN) of less than 50% were included in the study. Thus, we used the data of 16 prefectures (Iwate, Yamagata, Niigata, Tochigi, Chiba, Kanagawa, Toyama, Fukui, Aichi, Shiga, Tottori, Okayama, Hiroshima, Saga, Nagasaki, and Kumamoto), which are included in the 2008 MCIJ data. These data represent 33.1% of the Japanese population.

The period covered in this analysis was 1993 to 2008. In the Japanese cancer registry systems, disease incidence data are constructed and collected according to the International Classification of Diseases for Oncology (ICD-O) coding. The ICD-O-2 code was used up to and including 2002, while the ICD-O-3 code has been used since 2003. In the ICD-O-2, MDS was not considered a malignant disease but was rather coded as a neoplasm with uncertainty over whether it is in fact malignant, such that MDS was incidentally reported based on the definition of the local cancer registry. For the ICD-O-3, however, MDS was reclassified as a malignant disease and coded as 9980–9989. MDS coded by ICD-O-2 before 2002 have been re-coded in ICD-O-3 in each registry, so for the present study, we extracted MDS cases from the data using the ICD-O-3 code.

Incidence rates were standardized by age-adjustment to the world standard population and also to the 1985 Japanese model population, and rates were calculated for the number of newly diagnosed cases of MDS per 100,000 person-years as described in detail elsewhere. All analyses were performed with STATA version 11 (STATA Corporation, College Station, TX, USA).

RESULTS

A total of 7995 patients were reported to the data registries of 16 prefectures with newly diagnosed MDS from 1993 to 2008. The proportion of DCN cases were 46.6%. Median age at diagnosis was 76 years (interquartile range 68–82 years). Incidence sharply increased with age, particularly in those over age 70 years (Figure 1), with 3.1 cases per 100,000 men and 1.1 cases per 100,000 women in those aged 65–69 years versus 17.7 and 8.9 cases per 100,000, respectively, in those aged over 85 years.

Estimated annual age-standardized incidences of MDS during the study period are shown as circles in Figure 2, and the exact rates with 95% confidence intervals (CIs), which are the basis of Figure 2, are summarized in Table. Incidence showed male predominance, with nearly twice as many cases in men as in women. As shown in Figure 2, incidence significantly differed between 2002 and 2003, the year that the cancer registries in Japan started to use ICD-O-3. The most recent crude incidence rate of MDS is 3.8 (95% CI 3.6–4.1)

![Incidences of MDS in Japan](image-url)
per 100,000 for men and 2.4 (95% CI 2.2–2.6) per 100,000 for women in 2008. Age-adjusted incidences of MDS in 2008, standardized by the world standard population, were 1.6 and 0.8 cases per 100,000 for men and women, respectively, while incidences standardized by the 1985 Japanese population were 2.5 and 1.2 cases per 100,000 for men and women, respectively.

We initially aimed to evaluate MDS subtypes in detail, but 73% of cases in the registry were coded as MDS—not otherwise specified (code: 9989), leaving too few cases to evaluate incidence and trends by subtype.

**DISCUSSION**

The most recently reported age-adjusted incidence of MDS using the world population, of 1.6 cases per 100,000 for men and 0.8 cases per 100,000 for women in 2008, is less than half that in the U.S. and close to that in China. This difference among countries and races might suggest differences in risk exposure among countries or in genetic susceptibility among races. One of the most reliable cancer registries is the Surveillance Epidemiology and End Results (SEER), a population-based registry in the U.S., but a recent U.S. study reported that use of the SEER data resulted in a marked underestimation of the true incidence of MDS. Many patients with MDS are diagnosed at an advanced age and accordingly are no longer candidates for aggressive treatment such as allogeneic bone marrow transplant, which is the only treatment with curative potential. Instead, older MDS patients are offered supportive therapy with transfusion to maintain their quality of life. Except for the DNA-hypomethylating agents, cytotoxic chemotherapy does not prolong survival, so even the thorough evaluation and accurate diagnosis of MDS may not lead to effective treatment that results in a meaningful improvement in prognosis. Thus, it is possible that many elderly patients with cytopenia have not received sufficient diagnostic evaluation and have therefore not been diagnosed with MDS. In the U.S. study, the estimated incidence of MDS in elderly patients, using a new algorithm based on claims in the Medicare system, was nearly four-fold that estimated using the SEER data. Similar underestimation of incidence might also occur with the Japanese registry data. To get a more accurate understanding of the public health impact of MDS in Japan and reflect findings in public health policy and future research, more attention must be paid to the cancer registry system in Japan.

Previous studies of MDS based on case-series from Japan reported a median age at diagnosis of 57–60 years, which was significantly younger than in western countries. In contrast, the median age in the present study was 76 years, which is similar to that in western countries. Since cases in previous Japanese studies were collected at a centralized hospital, their diagnosis may reflect a degree of bias toward younger patients who required aggressive treatment.

We observed a dramatic increase in the incidence of MDS from 2002 to 2003, but this indicates a certain incompleteness in the early registry data of MDS (Figure 2) and is highly likely to be due to a change in the coding rule at this time. After the coding rule changed, incidence seems to have gradually increased in Japan since 2004. However, the reason for the increase in the incidence of MDS in Japan since 2004...
Table 1. Age-standardized incidence of MDS

| Year | 1993 | 1994 | 1995 | 1996 | 1997 | 1998 | 1999 | 2000 | 2001 | 2002 | 2003 | 2004 | 2005 | 2006 | 2007 | 2008 |

**Incidence of MDS in Japan**

The incidence of MDS in Japan has been increasing in the past two decades, particularly from 2003 onwards. This increase in incidence may be attributed to the increasing prevalence of obesity and smoking, as well as improvements in the detection and diagnosis of MDS. The male-to-female ratio of cases of MDS is around 2:1 in Japan, which is slightly higher than that in Western countries. The reasons for a higher male-to-female ratio of cases of MDS in Japan are hard to elucidate, but a lower consultation rate in the elderly female population may result in a lower rate of accurate diagnosis of MDS in this group.

In conclusion, the present study shows that the median age at diagnosis of MDS in Japan was similar to or even higher than that in western countries, but the incidence rate was lower. Nevertheless, MDS is a disease of the elderly that seldom receives a thorough evaluation for diagnosis. Substantial numbers of cases might have been dropped from the registry data, resulting in an underestimation of the real incidence of MDS in Japan. Accurate evaluation of the health impact of MDS in Japan requires evaluation of the mortality of the disease, continued surveillance, and improvement in the quality of the cancer registry data.
