Controlled degradation of low-fouling poly(oligo(ethylene glycol)methyl ether methacrylate) hydrogels†

Muhammad M. Shoaib, a Vincent Huynh, a Yousuf Shad, a Rashik Ahmed, b Alexander H. Jesmer, a,b Giuseppe Melacini d,ab and Ryan G. Wylie d,ac

Degradable low-fouling hydrogels are ideal vehicles for drug and cell delivery. For each application, hydrogel degradation rate must be re-optimized for maximum therapeutic benefit. We developed a method to rapidly and predictably tune degradation rates of low-fouling poly(oligo(ethylene glycol) methyl ether methacrylate) (P(EG)MA) hydrogels by modifying two interdependent variables: (1) base-catalysed crosslink degradation kinetics, dependent on crosslinker electronics (electron withdrawing groups (EWGs)); and, (2) polymer hydration, dependent on the molecular weight (M_w) of poly(ethylene glycol) (PEG) pendant groups. By controlling PEG M_w and EWG strength, P(EG)MA hydrogels were tuned to degrade over 6 to 52 d. A 6-member P(EG)MA copolymer library yielded slow and fast degrading low-fouling hydrogels suitable for short- and long-term delivery applications. The degradation mechanism was also applied to RGD-functionalized poly(carboxybetaine methacrylamide) (PCBMAA) hydrogels to achieve slow (~50 d) and fast (~13 d) degrading low-fouling, bioactive hydrogels.

1. Introduction

Degradable low-fouling hydrogels are being developed as implantable vehicles for drug and cell delivery to decrease the incidence rate of adverse events (e.g. foreign body response (FBR)) by minimizing non-specific protein adsorption and cell binding.1,2 The FBR cascade impedes drug release or cell egress from hydrogels by surrounding implants in dense fibrous capsules.3 Due to their strong hydration shells, non-specific protein adhesion to low-fouling polymers such as poly(oligo(ethylene glycol),methyl ether methacrylate) (P(EG)MA) and poly(carboxybetaine methacrylamide) (PCBMAA) is energetically unfavorable.4 P(EG)4–5MA coated surfaces resist protein fouling5 and platelet binding.6 Moreover, carboxybetaine coated surfaces have been shown to prevent non-specific protein adsorption in serum7 and resist the FBR for up to 3 months in vivo.8

The degradation of low-fouling hydrogels must be tuned to match requirements for short- and long-term delivery applications. Hydrogel drug delivery applications, such as cancer therapies,9–13 wound healing,14 pain management,11,14 and retinal degenerative disease treatments,15,16 often require drug release profiles that span a wide-distribution of timeframes, ranging from as little as a day to several weeks. We therefore require low-fouling hydrogels with highly tunable degradation timeframes. Predictable degradation rates are particularly important for long-term drug delivery (~4 weeks) wherein uncontrolled hydrogel degradation can limit efficacy by increasing the initial burst release.17 Thus far, degradation mechanisms for low-fouling gels have focused on endogenous triggers (e.g. reduction of disulfide bonds,19–22 enzyme cleavage sites23), or hydrolytic bonds (e.g. esters, hydrazones).24 In situ crosslinking P(EG)MA copolymers with aldehyde and hydrazide repeats yield hydrogels that crosslink through reversible hydrazone bonds with degradation rates proportional to pH and copolymer molecular weight (M_w).23,24 Carboxybetaine copolymers with zwitterionic thiol repeats have been developed to achieve biodegradable hydrogels in the presence of reducing agents such as glutathione.19,20,25 A detailed description of hydrogel degradation mechanisms is provided in the referenced review.26

Endogenous triggered degradation is dependent on dynamic biological environments, which may result in unpredictable degradation rates, and current methods to tune hydrolysis rates require extensive synthetic modifications. To improve therapies requiring low-fouling hydrogels, there is a great need to develop a versatile method to easily tune degradation rates that are independent of endogenous
triggers and don’t require additional synthetic steps. To achieve an accessible library of low-fouling hydrogels with varied degradation profiles, hydrogels should be formed by simply mixing a limited number of pre-defined polymers for in situ crosslinking. The combination of low-fouling P(EG)_xMA hydrogels of varying hydration levels with different crosslinkers for irreversible base-catalyzed degradation\textsuperscript{27,28} is expected to provide a method to rapidly tune degradation over clinically relevant timeframes. Irreversible base-catalyzed crosslink degradation\textsuperscript{27,28} is solely dependent on the pH of the implantation site, a known value, and not reliant on dynamic endogenous triggers. Furthermore, hydrogels composed of P(EG)_xMA with different PEG pendant group molecular weights (M\textsubscript{w}s) will exhibit different hydration levels to further tune base-catalyzed crosslinker degradation rates.\textsuperscript{29} By simply mixing pre-defined polymers, a library of P(EG)_xMA copolymers is expected to yield low-fouling hydrogels with highly tunable degradation kinetics.

2. Materials and methods

2.1 Materials

Triethylene glycol methyl ether methacrylate 93% ([(EG)\textsubscript{2}MA]), poly(ethylene glycol)methyl ether methacrylate number average molecular weight (M\textsubscript{n} 300) ([(EG)\textsubscript{0}MA]), poly(ethylene glycol) methyl ether methacrylate average M\textsubscript{n} 500 ([(EG)\textsubscript{0}MA]), 4-cyano-4-(phenylethanoxythiophen)-pentanoic acid (CTP), 4,4'-azobisis(4-cyanovaleric acid) (V-501), N-[3-(dimethylamino)propyl]methacrylamide (DMPMA), 4-chloro-1-hexanol, trifluoroacetic acid, >98% (APMA) was purchased from Polysciences, Inc. (Warrington, PA). 1,2-Bis(2,3-dihydro-1H-imidazol-2-yl)propan-2-yl)diazene dihydrochloride (VA-044) was purchased from Toronto Research Chemicals (Toronto, ON). Dibenzylcyclooctyne-NHS ester (DBCO-NHS) was gifted by Dr Alex Adronov at McMaster University (Hamilton, ON).

2.2 Synthesis and characterization of P(EG)\textsubscript{x}MA copolymers

2.2.1 Synthesis of P(EG)\textsubscript{x}MA copolymers with N-[3-aminopropyl]methacrylamide (P(EG)\textsubscript{x}MA-APMA). Inhibitors were removed from (EG)_xMA monomers using an aluminum oxide column. For P(EG)_xMA-APMA, (EG)_xMA (2 g, 8.6 mmol), APMA (81.0 mg, 0.44 mmol), CTP (5.8 mg, 21 \textmu mol) and VA-044 (1.35 mg, 4.18 \textmu mol) were dissolved in 2 : 1 water : dioxane (7 mL). For P(EG)_3MA-APMA, P(EG)_5MA (1 g, 3.3 mmol), APMA (48 mg, 0.27 \textmu mol), CTP (5.8 mg, 21 \textmu mol) and VA-044 (1.35 mg, 4.2 \textmu mol) were dissolved in 2 : 1 water : dioxane (2.5 mL). For P(EG)_6MA-APMA, P(EG)_8MA (1 g, 2 mmol) APMA (29 mg, 0.16 \textmu mol) were dissolved in 2 : 1 water : dioxane (1.1 mL) All reaction solutions were freeze-pump-thawed with a nitrogen backfill (3 times), and acidified to pH 3.5 using 0.1 M HCl prior to polymerization at 40 °C for ~16 h. Polymers were purified by dialysis (MWCO 12–14k) against pH 3 water and lyophilized to yield a pink paste (P(EG)_xMA-APMA: 1.325; P(EG)_4MA-APMA: 0.904; P(EG)_6MA-APMA: 0.948 g).

2.2.2 Characterization of P(EG)_xMA-APMA copolymers. Molecular weights (M\textsubscript{w}, M\textsubscript{n}) and polymer dispersity (D) of copolymers were determined using an Agilent 1260 Infinity II gel permeation chromatography (GPC) system equipped with an Agilent 1260 Infinity refractive index detector and GE healthcare Superose™ 6 Increase 10/30 GL column in 10 mM PBS running buffer. The column was calibrated with polyethylene glycol (PEG) standards (M\textsubscript{n} of 3 to 60 kDa). \textsuperscript{1}H NMR (600 MHz, D2O, 128 scans) of P(EG)_xMA-APMA and PCBMAA-APMA copolymers determined polymer APMA mole fractions by comparing the intensity of methylene peaks in each repeat unit (Fig. S1–S3†).

2.2.3 Synthesis of P(EG)_xMA-azide (P(EG)_xMA-MA) and P(EG)_xMA-DBCO copolymers. NHS-azide derivatives were synthesized as previously described,\textsuperscript{30} see ESI† for detailed protocols. P(EG)_xMA-APMA polymers were dissolved at 100 mg mL\textsuperscript{-1} in dry DMSO and reacted with NHS-azide or NHS-DBCO (1.2 eq. relative to amino groups) and triethyamine (3 eq.) overnight at room temperature. Complete amine consumption was confirmed by \textsuperscript{1}H NMR (Fig. S4–S15†) and a fluorescamine assay. Polymers were purified by dialysis (MWCO 12–14k) against water at pH ~ 3 and lyophilized to yield pink pastes. As seen in Scheme 1, three different P(EG)_xMA-Aszopolymers were prepared that contained a non-degradable (R1; H), slow-degrading (R2; 4-methylphenyl sulfone), or fast-degrading (R3; 4-chlorophenyl sulfone) carbamate bond for base-catalysed crosslink degradation.

2.2.4 Characterization of P(EG)_xMA-MA and P(EG)_xMA-DBCO copolymers. Copolymer cytotoxicity was assessed using NIH 3T3 mouse fibroblasts. Cells in DMEM/F12 media with 10% CBS were seeded in a 96 well plate at 5000 cells per well. Polymer solutions in PBS (sterilized using a 0.2 \mu m filter) were added to reach a final polymer concentration of 1 mg mL\textsuperscript{-1}. Cells were incubated at 37 °C, 5% CO\textsubscript{2} for 24 h. PrestoBlue reagent solution (22 \textmu L) was then added to each well and incubated at 37 °C, 5% CO\textsubscript{2} for 15 min. Fluorescence was measured using a BioTek Cytation 5 plate reader (\lambda_{ex} = 560 nm; \lambda_{em} = 590 nm). Copolymer lower critical solutions temperatures
(LCSTs) were determined by following the absorbance (600 nm) of polymer solutions (25 mg mL$^{-1}$) in pH 7.4 PBS or pH 9.3 0.1 M borax buffer in a 96 well plate over a temperature range of 30–65 °C and a ramp of 1 °C per 10 min on a BioTek Cytation 5 plate reader.

2.3 Gelation and characterization of P(EG)$_x$MA hydrogels

Gelation time was measured via gravitational flow analysis. Hydrogels (100 µL) were made with equal volumes and concentrations (50 mg mL$^{-1}$) of azide and DBCO copolymers. Vials were tilted periodically until flow was no longer observed. The number of crosslinks was determined by tracking the absorbance of 100 µL hydrogels (5 wt%) at 309 nm over time to measure consumption of DBCO over the first 24 h; gels were formed in a 96-well polypropylene plate. After 24 h, a 10-fold excess of sodium azide was added to react all remaining DBCO groups to determine background hydrogel absorbance. Hydrogel (5 wt%) cloud points were measured using the same procedure as for copolymer LCSTs.

Hydrogel swelling was determined by incubating 100 µL hydrogels (5 wt%) in pH 7.4 PBS at 37 °C for 22 h. The initial hydrogel wet weight was recorded. After selected time intervals, buffer was removed from hydrogel surfaces and their wet weight was recorded.

2.4 $^1$H NMR kinetic analysis of P(EG)$_x$MA–AZ–R3 copolymer degradation

$^1$H NMR spectra were recorded at 37 °C with 128 scans, 32 K complex points and spectral widths of 20 ppm on a Bruker 700 MHz spectrometer equipped with a TCI cryoprobe. All spectra were processed and analyzed in TopSpin 3.2.1. The base-catalyzed degradation of the polymers was assessed through the time-dependent increase in the $^1$H-NMR signal intensity of the nascent hydrolyzed product centred around ~7.8 ppm. For the purpose of comparison, the enhancement in the hydrolyzed product intensity was measured relative to the final intensity of the P(EG)$_x$MA–AZ–R3 hydrolyzed product at the end of the 3 h period. The resulting experimental points were used to create the kinetic profiles shown in Fig. 3D. The initial hydrolysis rate for P(EG)$_x$MA–AZ–R3 was determined by linear regression to compute the slope over the first 1 h period. To determine the initial hydrolysis rates of P(EG)$_x$MA–AZ–R3 and P(EG)$_x$MA–AZ–R3 copolymers, a linear regression was used to compute the slopes over the first 1 h period post lag phase (0.6 h); lag phase is defined as the initial period with no detectable hydrolysis.

2.5 Protein adsorption and cell adhesion on P(EG)$_x$MA hydrogels

2.5.1 Synthesis of BSA-fluorescein and RGD-AZ. For BSA-fluorescein synthesis, EDC (1.45 mg, 7.6 µmol) and NHS (0.87 mg, 7.5 µmol) were added to a fluorescein sodium salt (3.2 mg, 8.5 µmol) solution in 1 mL DMSO and incubated in the dark at room temperature for 25 min. Separately, 100 mg of BSA was dissolved in 9 mL of pH 7.4 PBS and combined with the NHS activated fluorescein solution. The solutions were reacted for 2 h at room temperature in the dark then dialyzed (MWCO 12–14k) against PBS in the dark at 4 °C. For RGD-AZ synthesis, CGRGDS (11 mg, 14 µmol) was dissolved in water (0.1 mL) with triethylamine (7.8 µL, 3 eq.). NHS-AZ (R1; 20 mg, 4 eq.) was dissolved in methanol (0.3 mL) and added to the peptide solution. The solution was reacted overnight at room temperature. The precipitate was collected by centrifugation and washed with water. The solid was dissolved in 0.1 M HCl, and the aqueous layer was washed with DCM (3 times). The aqueous layer was lyophilized to yield a white powder (3 mg). MS (ESI) analysis determined [M + 1]$^+$ peaks of 932.4 g mol$^{-1}$ for disubstituted peptide and 763.4 g mol$^{-1}$ for monosubstituted peptide.

2.5.2 BSA adsorption assay. P(EG)$_x$MA and PCBMAA hydrogels (60 µL, 5 wt%) were formed in triplicate in a 96-well plate and incubated at 37 °C for 5 h. PCBMAA–MC hydrogels were formed by mixing 10 wt% PCBMAA–DBCO dissolved in PBS with 0.5 wt% MC and 10 wt% PCBMAA–AZ–R1 dissolved in PBS with 0.5 wt% MC and gelled for 5 h at 37 °C. After
gelation, BSA-fluorescein (60 μL at 0.5 mg mL⁻¹) was pipetted onto gels and incubated at 37 °C for 2 h. The solution on top of the gels was removed and gels were rinsed 3 times with PBS. Gels were immersed in 240 μL of 1 × PBS with 0.08 wt% SDS and incubated overnight. The mixture was then sonicated for 30 min to extract residual BSA-fluorescein and the fluorescence was measured using a BioTek Cytation 5 plate reader (λex = 494 nm; λem = 521 nm). The concentration was determined using a BSA-fluorescein calibration curve of known concentrations.

2.5.3 Cell adhesion assays. 60 μL hydrogels (5 wt%) in pH 7.4 PBS were formed in a 96 well plate and allowed to gel for 5 h at 37 °C. RGD-AZ (60 μL, 1 mg mL⁻¹ in PBS) was added on top of the hydrogels and incubated overnight at 4 °C. Gels were then immersed in PBS for 2 d at 4 °C to remove unreacted RGD-AZ. 5000 NIH 3T3 mouse fibroblasts in DMEM/F12 with 10% CBS were seeded on top of each hydrogel (with and without RGD-AZ) and incubated for 24 h at 37 °C, 5% CO₂. Cells were then stained with Calcein AM and Hoechst, as per the manufacturer’s protocol. Gels were then rinsed with PBS (3 times) to remove non-adhered cells and imaged using a BioTek Cytation 5 cell imager.

3. Results and discussion

We developed low-fouling P(EG)₉MA hydrogels with tunable degradation rates by controlling two interdependent variables: (1) base-catalysed crosslink degradation kinetics, dependent on the strength of the incorporated electron withdrawing group (EWG; Fig. 1A); and, (2) polymer hydration, dependent on the MW of PEG pendant groups (Fig. 1B). By combining P(EG)₉MAs with different PEG pendant groups (x = 3, 4, 5, and 8–9) with two different crosslinkers (EWG = 4-methylphenyl sulfone or 4-chlorophenyl sulfone), we developed a 6-member copolymer library to rapidly tune P(EG)₉MA hydrogel degradation over 6, 13, 31, or 52 d, yielding gels suitable for short- and long-term applications (Fig. 1C). We also demonstrated the degradation of RGD functionalized low-fouling PCBMAA hydrogels over 13 and 52 d to produce bioactive, low-fouling gels for cell delivery applications.

3.1 Synthesis and chemical characterization of P(EG)₉MA copolymers

Because P(EG)₉MA is synthesized by controlled radical polymerization, monomers with reactive functional groups can be

---

Fig. 1  Schematic highlighting the short- and long-term degradation of low-fouling hydrogels from a library of P(EG)₉MA copolymers with two different crosslinkers. (A) Irreversible base-catalyzed hydrolysis of carbamate crosslinks tuned with two different EWGs (4-methylphenyl sulfone and 4-chlorophenyl sulfone). Deprotonation site is highlighted by a red circle. (B) The MW of PEG pendant groups in P(EG)₉MA influenced hydrogel degradation rates. (C) Tunable hydrogel degradation from 6 to 52 days was achieved by creating a library consisting of 3 P(EG)₉MA copolymers and two different EWGs. Lower PEG MW (less hydrated) P(EG)₉MAs and weaker EWGs produced slower degradation rates.
polymerized into P(EG)MA copolymers for in situ crosslinking and controlled degradation. We first synthesized random P(EG)MA copolymers with N-(3-aminopropyl)methacrylamide (APMA) using reversible addition–fragmentation chain-transfer (RAFT) polymerization to yield P(EG)MA–APMA with $M_n$ and dispersities ($D$) between 30–40 kDa and 1.06 to 1.35, respectively (Scheme 1; Table 1). P(EG)MA–APMA copolymers with different PEG pendant groups ($x = 3, 4–5$, and $8–9$), were prepared to determine the influence of polymer hydration on hydrogel degradation.

The (EG)MA to APMA composition in copolymers was optimized to ensure similar crosslink densities (crosslinks per g of polymer) in all P(EG)MA hydrogels, which allowed for the comparison of polymer hydration on degradation rates. To this end, P(EG)MA–APMA, P(EG)$_{4}$–MA–APMA, and P(EG)$_{8}$–9MA–APMA were synthesized with 2, 5, and 10 APMA mol%, respectively, as confirmed by $^1$H NMR upon comparing integrations of methylene peaks in (EG)MA and APMA (Table 1; Fig. S1–S3†). Due to steric associated with PEG pendant groups, greater crosslinker mole fractions, and thus APMA, were required for P(EG)MAs with higher PEG $M_n$ to standardize crosslink density.

Table 1 P(EG)$_{x}$MA–APMA $M_n$, $D$ and composition

| Polymer     | $M_n$ (kDa) | $D$ | APMA (mol%) |
|-------------|-------------|-----|-------------|
| P(EG)$_{2}$MA–APMA | 33.5        | 1.35 | 2           |
| P(EG)$_{4}$–MA–APMA | 30.7        | 1.11 | 5           |
| P(EG)$_{8}$–9MA–APMA | 36.8        | 1.18 | 10          |

$^a$ $M_n$ and $D$ determined by GPC calibrated with PEG standards.

To compare polymer hydration through solvation, we studied the solubility of P(EG)$_{2}$MA and P(EG)$_{4}$–5MA copolymers as a function of temperature and determined LCSTs (Fig. 2, S21A and B†). A homopolymer (HP) of P(EG)$_{2}$MA had an LCST of 45 °C (25 g L$^{-1}$), defined as the onset of cloudiness. In comparison to the HP, all P(EG)$_{2}$MA–AZ and P(EG)$_{2}$MA–DBCO copolymers demonstrated lower LCSTs near physiological temperature (36–37 °C) due to increased hydrophobic content. The HP of P(EG)$_{4}$–MA and P(EG)$_{8}$–9MA–AZ copolymers had LCSTs of 62 and 52–54 °C, respectively. Interestingly, P(EG)$_{4}$–MA–DBCO’s LCST was 2 °C lower than the P(EG)$_{4}$–MA HP and 6–8 °C higher than P(EG)$_{4}$–5MA–AZs. Therefore, the increased hydrophobic content from DBCO did not substantially influence P(EG)$_{4}$–5MA’s temperature-dependent solubility, indicating a DBCO composition greater than 5 mol% is required to influence P(EG)$_{4}$–5MA’s LCST. Due to larger PEG side chains, P(EG)$_{8}$–9MA copolymers did not exhibit an aqueous LCST (Fig. S21C†) when heated to 65 °C. Copolymer LCSTs will also predict hydrogel fouling properties as copolymers with LCSTs near or above body temperature will maintain their low-fouling properties; hydrogels are fouling at temperatures above their LCSTs due to increased hydrophobic interactions with proteins.

3.2 $^1$H NMR kinetic analysis of P(EG)$_{2}$MA–AZ carbamate degradation

To probe the influence of PEG $M_n$ on carbamate degradation kinetics, $^1$H NMR spectra of P(EG)$_{2}$MA–AZ–4 copolymers with the 4-chlorophenyl sulfone EWG (P(EG)$_{2}$MA–AZ–R3) were acquired in real time for 3 h in borate buffer at pH 9.3, which increased reaction rates for efficient NMR analysis. Degradation was monitored by peak intensity changes of aromatic protons in 4-chlorophenyl sulfone, which is cleaved from the polymer upon hydrolysis. Over the course of the 3 h experiment, time-dependent losses in signal intensity were observed for polymer bound 4-chlorophenyl sulfone (aromatic protons, 7.8–8.1 ppm) and intensity gains for cleaved 4-chlorophenyl sulfone (aromatic protons, dashed box, sharp doublet, ±7.8 ppm; Fig. 3A–C).

The degradation rate of P(EG)$_{2}$MA–AZ–R3 copolymers were dependent on the PEG $M_n$. P(EG)$_{8}$–9MA–AZ–R3 degraded immediately due to its higher solubility (LCST > 65 °C; Fig. 3D). In contrast, P(EG)$_{4}$–5MA–AZ–R3 exhibited a lag phase (~0.6 h) with no detectable degradation followed by a degradation rate similar to P(EG)$_{8}$–9MA–AZ–R3 (slopes of images for Table 1 and Fig. 2).
The biphasic degradation profile of P(EG)₄–₅MA–AZ–R₃ is a function of polymer solubility over time; the cleavage of hydrophobic 4-chlorophenyl sulfone increases P(EG)₄–₅MA–AZ–R₃ solubility. Only minor P(EG)₃MA–AZ–R₃ degradation was observed over the 3 h time period (Fig. 3A and D) because of its lower solubility at 37 °C, which is supported by LCST data (Fig. 2 and S22A†). From P(EG)₄–₅MA–AZ–R₃ data, we can conclude that PEG Mₓ mainly influences initial degradation rates.

3.3 Cytotoxicity of P(EG)ₓMA copolymers

All P(EG)ₓMA copolymers were non-cytotoxic according to NIH 3T3 fibroblast cell viability assays (Fig. 4). Cells were cultured in DMEM/F12 media with 10% calf bovine serum (CBS) in the presence of a single copolymer (1 mg mL⁻¹). After 24 h, cell viability was determined using the PrestoBlue assay and compared to a positive control, cells cultured without polymer. All copolymer conditions were indistinguishable from the positive control, indicating copolymers are non-cytotoxic and suitable for hydrogel fabrication.
3.4 Hydrogel gelation and characterization

Non-degradable P(EG)$_x$-MA–AZ copolymers were mixed with corresponding P(EG)$_x$-MA–DBCO copolymers for in situ gelation and characterization of hydrogel crosslink density, swelling and protein fouling. Hydrogels were prepared by mixing equal volumes of corresponding azide and DBCO copolymer solutions (5 wt% in PBS) for strain-promoted alkyne–azide cycloaddition (SPAAC) crosslinking, and gelation times were determined by gravitational flow analysis (Fig. 5A); gelation time increased with larger PEGs, which limits crosslinking rates due to steric effects.

To study the influence of polymer hydration (PEG $M_W$) on hydrogel degradation, all P(EG)$_x$-MA hydrogels (P(EG)$_3$-MA, P(EG)$_4$–5-MA, and P(EG)$_8$–9-MA) required similar crosslink densities. The density of hydrogel crosslinks (μmol per g of polymer) was determined by quantifying DBCO consumption after SPAAC crosslinking (Table 2); unreacted DBCO absorbs light at 309 nm with an extinction coefficient of 12 000 M$^{-1}$ cm$^{-1}$. To achieve P(EG)$_x$-MA hydrogels with similar crosslink densities, copolymer precursors with different AZ and DBCO mole fractions were required due to unique crosslinking kinetics. P(EG)$_3$-MA, P(EG)$_4$–5-MA, and P(EG)$_8$–9-MA required crosslinker mole fractions of 2, 5, and 10 mol%, respectively, to yield hydrogels with similar crosslink densities (47–52 μmol of crosslinks per g of polymer).

Crosslink densities were determined by measuring unreacted DBCO concentrations (absorbance at 309 nm) after an overnight incubation to ensure maximum crosslinking. To calculate hydrogel background absorbance, all gels were subsequently exposed to excess sodium azide to consume remaining DBCOs.

To compare hydration of P(EG)$_x$-MA hydrogels, hydrogel cloud points and swelling ratios were determined. The cloud points of non-degradable (R1) and degradable (R2, Fig. 5B, S23A and B†) P(EG)$_3$-MA and P(EG)$_4$–5-MA hydrogels were similar to their corresponding P(EG)$_x$-MA–AZ and P(EG)$_x$-MA–DBCO copolymers; P(EG)$_3$-MA and P(EG)$_4$–5-MA hydrogels had cloud points of 36 and 54 °C, respectively. As expected from P(EG)$_8$–9-MA copolymer LCSTs, P(EG)$_8$–9-MA gels did not exhibit a cloud point (Fig. S23C†). In agreement with hydrogel cloud points, the equilibrium swelling ratio of P(EG)$_x$-MA hydrogels

![Fig. 5](image-url)  Characterization of non-degradable P(EG)$_x$-MA hydrogels: gelation time, hydration and protein fouling. (A) Hydrogel (5 wt%) gelation time, determined by gravitational flow analysis (mean ± standard deviation, $n = 6$). (B) Cloud point of P(EG)$_3$-MA and P(EG)$_4$–5-MA hydrogels (5 wt% in PBS) defined as the onset of turbidity (600 nm). No cloud point was observed for P(EG)$_8$–9-MA gels. (C) Equilibrium swelling of non-degradable gels. After overnight gelation, hydrogels (5 wt%) were submerged in PBS and their wet weight was determined at specified time points (mean ± standard deviation, $n = 3$). (D) Adsorbed fluorescent BSA (μg cm$^{-2}$) on hydrogel surfaces compared to low-fouling PCBMAA gels (6 mol% AZ/DBCO) and fouling PCBMAA–MC gels (mean ± standard deviation, $n = 3$).
increased with greater PEG \( M_W \) (Fig. 5C). P(EG)\(_3\)MA gels incubated at 37 °C shrunk by expelling \( \sim 40\% \) of their initial water content, due to the promotion of polymer-polymer interactions at temperatures near its cloud point (36 °C). P(EG)\(_4\)–5MA (cloud point 54 °C) and P(EG)\(_8\)–9MA hydrogels swelled to \( \sim 160\% \) and 200\%, respectively, of their initial wet weight.

To ensure P(EG)\(_x\)MA retained their low-fouling properties, we quantified the non-specific adsorption of fluorescent BSA to hydrogel surfaces. Non-degradable hydrogels were incubated in 0.5 mg mL\(^{-1}\) fluorescent BSA solutions for 2 h and rinsed with PBS. Adsorbed fluorescent BSA was extracted from the hydrogels with a sodium dodecyl sulfate (SDS) solution for quantification.\(^{22}\) All gels bound between 5 and 10 \( \mu g \) cm\(^{-2}\) of fluorescent BSA, similar to other low-fouling hydrogels.\(^{22}\)

### 3.5 Tunable degradation of P(EG)\(_x\)MA hydrogels

By developing a library of P(EG)\(_x\)MA–AZ and P(EG)\(_x\)MA–DBCO copolymers with R2 and R3 crosslinkers, we were able to easily achieve hydrogel degradation over 6 to 52 d (Fig. 6). Degradation rates were controlled by polymer hydration (P(EG)\(_3\)MA, P(EG)\(_4\)–5MA, and P(EG)\(_8\)–9MA) and the acidity of the crosslinker’s \( \beta \)-hydrogen by exchanging EWG groups (4-methylphenyl sulfone or 4-chlorophenyl sulfone). Because PEG \( M_W \) influenced degradation rates (Fig. 3), each crosslinker (R2 or R3) yielded three different hydrogel degradation profiles. Hydrogels with higher PEG \( M_W \) degraded faster due to greater polymer solvation and initial degradation rates, as demonstrated by hydrogel swelling (Fig. 5C) and \(^1\)H NMR kinetic studies (Fig. 3). For example, P(EG)\(_3\)MA–R3, P(EG)\(_4\)–5MA–R3 and P(EG)\(_8\)–9MA–R3 gels degraded over 52, 13 and 6 d, respectively (Fig. 6). As expected, P(EG)\(_x\)MA hydrogels degraded faster with crosslinks containing the stronger EWG (4-chlorophenyl sulfone, R3).

P(EG)\(_x\)MA hydrogels, which shrunk over time (Fig. 5C), produced the slowest degradation profiles (Fig. 6A and D). P(EG)\(_3\)MA–R3 gels degraded over 52 d, 4-fold slower than P(EG)\(_4\)–5MA–R3 gels. Therefore, PEG \( M_W \) has a significant impact on hydrogel degradation timeframes. Interestingly, P(EG)\(_1\)MA–R2 gels remained intact for >120 d. We expect P(EG)\(_3\)MA–R2 gels to eventually degrade because P(EG)\(_3\)MA–R3 gels degraded, which indicates that crosslink deprotonation and cleavage occur in P(EG)\(_3\)MA gels. Therefore, the design of P(EG)\(_x\)MA gels that degrade over 6 to >120 d may be possible using the developed copolymer library. Because

---

**Fig. 6** Tunable degradation of P(EG)\(_x\)MA hydrogels at pH 7.4. The combination of different P(EG)\(_x\)MA copolymers with R2 or R3 crosslinkers yields low-fouling hydrogels that degrade over 6 to 52 d. The degradation of (A) P(EG)\(_3\)MA, (B) P(EG)\(_4\)–5MA, and (C) P(EG)\(_8\)–9MA hydrogels (100 \( \mu L \), 5 wt\%) with R2 (4-methylphenyl sulfone) or R3 (4-chlorophenyl sulfone) crosslinkers was followed over time in pH 7.4 PBS at 37 °C (mean ± standard deviation, \( n = 3 \)). (D) Illustration summarizing time required for complete degradation of each hydrogel.
3.6 P(EG)$_x$MA gels are non-cell adhesive

Non-specific binding of cells to hydrogels can impede drug and cell delivery. To demonstrate P(EG)$_x$MA gels are resistant to non-specific cell adhesion, non-degradable P(EG)$_x$MA gels were exposed to fibroblasts in 10% CBS in DMEM/F12 media. After 24 h, gel surfaces were gently washed with PBS to remove non-
adhered cells. After staining with Calcein AM and Hoechst, micrographs of cells on gel surfaces were collected. No adhered cells were detected on any P(EG) x MA gel (Fig. 7A), indicating the gels are low-fouling towards cells. PCBMAA gels formed through in situ PCBMAA–AZ and PCBMAA–DBCO (6 mol% AZ/DBCO) crosslinking were included as controls; PCBMAA gels are known to resist non-specific cell binding \(^a\) (Fig. 7A).

P(EG) y MA gels modified with RGD cell adhesion peptides demonstrated limited cell adhesion, indicating P(EG) y MA gels also hindered integrin mediated adhesion. Excess DBCO groups in P(EG) y MA gels were modified with an RGD-AZ peptide; the reaction was monitored by decreasing DBCO absorbance (309 nm; data not shown). Fibroblasts were seeded on hydrogel surfaces and incubated for 24 h. Cells were then stained with Calcein AM and Hoechst gels, gently washed with PBS to remove non-adhered cells, and gel surfaces were imaged. Only small cell clusters were observed on RGD modified P(EG) y MA gels indicating weak RGD mediated cell–hydrogel interactions (Fig. 7B). In contrast, cells adhered to RGD modified PCBMAA gels (Fig. 7B) with morphologies similar to cells on tissue culture plastic (TCP; Fig. S25\(^\dagger\)). PCBMAA polymers are known to promote protein–ligand interactions, \(^2\) whereas the PEG pendant groups in P(EG) y MA may hinder protein–ligand complexation; PEG polymers are known to decrease enzymatic activity. \(^2\) Because all hydrogels contained a large excess of DBCO groups (>100 nmol cm\(^{-2}\) on the surface) for RGD immobilization, all hydrogel surfaces had sufficient RGD for cell adhesion (>1 fmol cm\(^{-2}\)). \(^4\) Therefore, P(EG) y MA gels are ideal for applications that require minimal protein and cell binding.

For some stem cell delivery applications, degradable hydrogels functionalized with adhesive peptide have been shown to improve cell survival. \(^3\) Therefore, we incorporated the two crosslinkers (R2 and R3) into PCBMAA hydrogels (Scheme S1\(^\dagger\)), which degraded over 13 and 52 d (Fig. S24\(^\dagger\)). Due to the high solubility of PCBMAA copolymers, the rate of PCBMAA hydrogel degradation was expected to be similar to P(EG) x–y MA gels, which degraded over 6 and 31 d. The slower degradation rate was attributed to PCBMAA’s greater cross-link density than P(EG) x–y MA gels (128 vs. 48 \(\mu\)mol g of polymer). Therefore, the PCBMAA hydrogel can be used for short- and long-term applications that require bioactive hydrogels.

3.7 Further discussion

The developed degradation mechanism for low-fouling P(EG) y MA gels tuned the deprotonation rate of the carbamate crosslinker independently from endogenous triggers by changing EWGs and PEG \(M_\text{w}\), which provides a method to reliably achieve different hydrogel degradation timeframes. All components, except for released CO\(_2\), remain covalently bound to degraded non-cytotoxic copolymers, we therefore expect minimal \(\textit{in vivo}\) toxicity for future applications. Moreover, all degradation timeframes (6, 13, 31, and 52 d) can be achieved from highly soluble P(EG) x–y MA and P(EG) x–y MA copolymers (LCSTs > physiological temperature) and will therefore remain soluble after hydrogel degradation to further improve biocompatibility.

Controlled degradation of hydrogels is important for drug and cell delivery. For example, the sustained release of antibody checkpoint inhibitors for \(\sim\)1 week from degradable poly(vinyl alcohol) hydrogels improved survival in a melanoma mouse model by 50% over intravenous injections. \(^4\) Adoptive cell therapies are improved by creating a local cell depot with injectable hydrogels that degrade to allow for cell egress. Hydrogels have been shown to improve transplantation efficiency of neural stem cells \(^4\) and T cell infiltration \(^2\) into tumors for cancer immunotherapies. The ability to control hydrogel degradation will improve adoptive cell therapies by controlling the rate of cell egress from the hydrogel into surrounding tissue. Therefore, we demonstrated that encapsulated fibroblasts in P(EG) y MA gels retained high viability to ensure the crosslinking mechanism is not cytotoxic (Fig. S26\(^\dagger\)); SPAAC crosslinking has previously been demonstrated to be non-cytotoxic. \(^4\) To avoid unwanted adverse events (e.g. FBR), low-fouling hydrogels that degrade over several days to weeks are required, such as those developed here.

The degradation rate of P(EG) y MA gels will influence both drug and cell delivery. For the developed P(EG) y MA gels, cells seeded on the surface of RGD modified hydrogels did not migrate into the gel, indicating hydrogel pore sizes are sub-micron and prevent cell migration. Therefore, the degradation rate of the P(EG) y MA gels will be the main determinant for cell delivery rates. However, hydrogel degradation will not be required for drug efflux because P(EG) y MA gels with similar and higher crosslink densities have previously been demonstrated to release proteins for drug delivery applications. \(^4\) Although, faster degradation rates will increase rates of drug release.

4. Conclusions

The developed 6-member P(EG) y MA copolymer library allows for the rapid fabrication of low-fouling hydrogels that degrade over 6 to 52 d, which will be useful for short- and long-term drug and cell delivery applications. Furthermore, P(EG) y MA–R2 may result in hydrogels that degrade over \(>120\) d. The combination of tunable base-catalyzed crosslink degradation and P(EG) y MA hydration provides a simple method to rapidly tune degradation rates. Given that the non-cytotoxic P(EG) y MA gels remained low-fouling towards proteins and cells, it is expected that they will help mitigate adverse immune responses (e.g. FBR) upon implantation. Interestingly, P(EG) y MA gels modified with RGD remained non-cell adhesive by preventing integrin mediated adhesion. The established low-fouling P(EG) y MA hydrogel library that easily achieves different degradation timeframes will expedite the establishment of drug and cell delivery therapies.
