I. INTRODUCTION

Although a substantial amount of work has been carried out on the assumption of a ‘standard’ cosmology, in which the Universe proceeds from an early period of inflation through reheating to radiation domination and finally to matter domination in the recent past, there is no direct evidence supporting this picture until the relatively late epoch at which nucleosynthesis occurs. Recently, this standard picture has been questioned and some alternative cosmologies discussed. An example is ‘thermal inflation’[1], a short second period of inflation at lower energy scales which does not generate interesting density perturbations, but which may resolve additional relic density problems not solved by the original inflationary period.

Several cosmological constraints are sensitive to whatever assumption is made for the entire cosmological evolution: axion cosmology is one such situation[1], and the constraints originating from primordial black holes (PBHs) is another. Recently, the latter was reinvestigated for cosmologies with thermal inflation, showing that the standard constraints on the formation density of PBHs would weaken quite markedly[3].

Another possible modification to the standard cosmology is the addition of a prolonged period of matter domination, induced by a slow-decaying massive particle. In $N = 1$ supergravity models[2], supersymmetry (SUSY) is broken in some hidden sector and the gravitational strength force plays the role of messenger by transmitting SUSY breaking down to the visible sector. In these models there often exist scalar fields with masses of the order of the weak scale and gravitational strength coupling to the ordinary matter. If at early epochs one of these fields is sitting far from the minimum of its potential with an amplitude of order of the Planck scale, the coherent oscillations about the minimum will eventually dominate the energy density of the universe. These fields will then behave like nonrelativistic matter, and decay at very late times. The presence of these slow-decaying massive particles is predicted not only in some specific classes of supergravity models, but in almost all theories in which supersymmetry is broken at an intermediate scale. In string models, massless fields exist in all known string ground states and parametrize the continuous ground state degeneracies characteristic of supersymmetric theories. These fields are massless to all orders in perturbation theory, and get their mass, of order a TeV, from the same non-perturbative mechanism which breaks SUSY. Being coupled to the ordinary matter only by gravitational strength couplings, a long lifetime results. Possible examples are the dilaton of string theory and the massless gauge singlets of string compactifications, and they go generically under the name of moduli. Under natural assumptions on the couplings, one finds that the reheating temperature after the moduli decay is too low to allow standard nucleosynthesis. Therefore, moduli are generally far too good at giving a period of matter domination, lasting beyond the epoch of nucleosynthesis and destroying this crucial success of the standard cosmology[7].

Many attempts have been made to resolve this cosmological moduli problem[4]. However, all of them require new phenomena to occur on the cosmological side as well as in the theory of supersymmetry breaking. It is not our intention, in this paper, to propose another solution to the moduli problem, but rather to study the extent to which the modular cosmology may affect the standard primordial black hole constraints. We will therefore assume that the moduli are somewhat more massive than the supersymmetry scale set by the gravitino mass $m_{3/2} = (10^2 - 10^3)$ GeV, and that their decay can be
just early enough. This assumption seems reasonable in view of the recent developments in the context of the field-theory limit of superstrings \[1\], where it has been shown that moduli masses as large as $10^2 m_{3/2}$ can be achieved without incurring excessive unnaturalness. The cosmological sequence in such a model is as follows. At a high temperature the moduli come to dominate and the Universe begins an epoch of matter–domination. During this period, the radiation field actually cools to some way below the nucleosynthesis scale (about $10^{-3}$ GeV), but the moduli decay while the energy density is still high enough to permit thermalization slightly above the nucleosynthesis temperature. In this picture, baryogenesis must be caused by the decay of the moduli, rather than at the electro-weak transition \[1\].

II. THE MODULI–DOMINATED EPOCH

In hidden-sector models, supersymmetry breaking is conveyed to the low-energy visible sector through Planck scale suppressed interactions. In non-renormalizable hidden-sector models, supersymmetry vanishes in the limit $m_{P1} \to \infty$, $m_{P1}$ being the Planck mass. Since the potential for a generic moduli field $\phi$ is generated through the same physics associated to supersymmetry breaking, its potential takes the form

$$V(\phi) = m_{3/2}^2 M_{P1}^2 V(|\phi|/M_{P1}), \quad (1)$$

where $M_{P1} = m_{P1}/\sqrt{8\pi}$ is the reduced Planck mass and $m_{3/2} \sim 1$ TeV is the gravitino mass. The potential for this dangerous direction vanishes in the flat-space limit since $m_{3/2} \to 0$ in that limit. As mentioned in the introduction, excitations around the zero-temperature minimum $\phi_0$ of the potential have a mass $m_\phi = \mathcal{O}(10^3) m_{3/2}$.

Moduli fields are expected to be initially shifted from their zero-temperature minimum due to the effect of thermal fluctuations or of quantum fluctuations during inflation \[2\]. Another source of the shift might be the fact that the moduli couplings to the inflaton generally modify, during inflation, the properties of the effective potential. Moduli usually acquire a mass squared of the order of $H^2$, where $H \sim 10^{13}$ GeV is the Hubble parameter during the inflationary stage, and the value of the minimum of the potential may be shifted \[3\]. The shift produced by such effects may be as large as $m_{P1}$.

Although the form of the potential is not known, for our purposes one may just consider oscillations around the minimum with initial amplitude $\phi_i$ and take $V(\phi) \simeq m_\phi^2 \phi^2/2$. When the Hubble parameter $H$ reaches a value $H \sim m_\phi$, the scalar field starts oscillating coherently around the minimum of the potential. This happens when the temperature of the universe is $T_{\text{reh}} \sim \sqrt{m_\phi m_{P1}}$ (in the case in which the universe is radiation dominated at that epoch).

The initial energy stored in the oscillations $\rho_i \sim m_\phi^2 \phi_i^2$ redshifts like matter and can eventually dominate the energy density. When it does so depends on $\phi_i$. If $\phi_i$ is of order $m_{P1}$, then the moduli dominate immediately, while if $\phi_i$ is smaller, radiation domination will continue for a while before the moduli come to dominate, or, in extreme cases, the moduli may decay before they dominate the energy density. In hidden-sector models, moduli couple to other fields only through Planck suppressed interactions. Examples of such fields are the dilaton and the compactification moduli of string theory, or, in general, for any gauge singlet field responsible for SUSY breaking. There are several types of Planck suppressed couplings the moduli might have with ordinary matter, but all of them lead to the same estimate of the decay width

$$\Gamma_\phi \sim \frac{m_\phi^3}{m_{P1}^{1/2}}. \quad (2)$$

The condition for the moduli to dominate the energy density of Universe when they decay (which will be at the epoch $H \simeq \Gamma_\phi$) is that their initial value satisfies

$$\phi_i \gtrsim 10^{-8} \left(\frac{m_\phi}{1 \text{ TeV}}\right)^{1/2} m_{P1}. \quad (3)$$

At the decay time the radiation fluid has temperature

$$T_{\text{dec}} \sim m_\phi^{11/6} \phi_i^{-1/6} m_{P1}^{-2/3}. \quad (4)$$

The decay products of the moduli will thermalize, reheating the universe up to a temperature

$$T_{\text{reh}} \sim \frac{m_\phi^{3/2}}{m_{P1}^{1/2}} \sim 3 \times 10^{-4} \left(\frac{m_\phi}{10^2 \text{ GeV}}\right)^{3/2} \text{ MeV}. \quad (5)$$

Notice that the reheating temperature is independent of $\phi_i$, provided that the universe is dominated by the moduli energy density when decays start.

The decay products of $\phi$ will destroy the $^4$He and D nuclei, and thus successful nucleosynthesis predictions, unless $T_{\text{reh}}$ is larger than about 1 MeV. If the moduli field has mass $10^2$ GeV, $T_{\text{reh}}$ is well below the energy scale of nucleosynthesis, but if instead one assumes $m_\phi \sim 10^3$ GeV, then the reheat temperature becomes comparable and it may be possible to thermalize to a high enough temperature for standard nucleosynthesis to proceed. In the case $\phi_i \sim m_{P1}$ where the moduli dominate as soon as they begin to oscillate, this corresponds to an expansion of the Universe during matter domination by a factor of around $(m_{P1}/m_\phi)^{4/3} \sim 10^{20}$, a very prolonged period indeed.

III. PRIMORDIAL BLACK HOLE CONSTRAINTS

A. Formation density constraints

In a radiation–dominated Universe at temperature $T$, the horizon mass is given roughly by
PBHs of a given mass are expected to form around the time when that mass equals the horizon mass; production of smaller black holes is suppressed as pressure prevents the collapse of any density perturbation. In a matter-dominated Universe, formation may occur on scales below the horizon mass, as we discuss later.

The lifetime of the black hole can be parametrized as

\[ \tau_{\text{evap}} = \frac{9 \times 10^{-27}}{f(M)} \left( \frac{M}{1 \text{g}} \right)^3 \text{sec}, \tag{7} \]

where \( f(M) \) depends on the number of particle species which can be emitted and is normalized to 1 for holes which emit only massless particles. A black hole of initial mass around \( 5 \times 10^{14} \text{g} \) would be evaporating at the present epoch, while masses around \( 10^{10} \text{g} \) would be evaporating at nucleosynthesis.

Those lighter black holes may form early on in the period of moduli domination, or even before it if its onset is delayed.

We denote the fraction of the density of the Universe in black holes of a given mass as \( \beta \), with \( \beta_i \) denoting the initial density at formation. The ratio of the PBH density to the density in other forms is denoted \( \alpha \equiv \beta/(1-\beta) \).

The various limits which can be placed on the PBH density are well known [3,4]; we shall use the compilation given in Ref. [5]. There are a range of constraints from effects of evaporation, while for more massive black holes, \( M \gtrsim 10^{15} \text{g} \), the only limit comes from their contribution to the present density parameter. An additional, less secure constraint arises if one assumes that evaporation leaves behind a Planck mass relic [15].

All these constraints are expressed as limits on the fraction of the mass of the Universe in black holes at the present or at the time of evaporation. To constrain the initial mass fraction, one needs to assume a form for the entire cosmology back to the formation epoch, given by Eq. (6), Fig. 1 shows the result of carrying this out for the standard cosmology, where the Universe was radiation dominated until very recently [3]. We see that the constraints are extremely tight; typically only something like \( 10^{-20} \) of the mass of the Universe is permitted to form black holes in the standard cosmology.

We now turn to our main purpose, examining the change in the constraints induced by a period of moduli domination. In order to attain a reheating temperature of \( T_{\text{reh}} \sim 10^{-3} \text{GeV} \), so that nucleosynthesis can proceed, we require \( m_\phi \sim 2 \times 10^4 \text{GeV} \). In the extreme case of \( \phi_i \sim m_{\text{Pl}} \), the moduli begin to oscillate at temperature \( T_{\text{MD}} \sim 2 \times 10^{11} \text{GeV} \), since

\[ \rho_i = m_\phi^2 m_{\text{Pl}}^2 = \frac{\pi^2}{30} g_*^{\text{MD}} T_{\text{MD}}^4. \tag{8} \]

Here \( g_*^{\text{MD}} \sim 250 \) is the number of degrees of freedom in the minimal supersymmetric standard model. In the following, we will consider two scenarios: one in which \( \phi_i \sim m_{\text{Pl}} \) and moduli domination begins immediately, and an intermediate scenario where \( \phi_i \sim 10^{-4} m_{\text{Pl}} \) and there is a delay before moduli domination commences.

1. Immediate moduli domination

From Eq. (6), PBHs in the mass range \( 2 \times 10^9 \text{g} \leq M \leq 2 \times 10^{30} \text{g} \) are formed during the moduli-dominated era. During moduli-domination, the PBHs constitute a constant fraction of the total energy density. The time of the decay of the moduli, \( t_{\text{dec}} \), and of the reheating of the subsequent thermalized fluid, \( t_{\text{reh}} \), can be taken as the same, giving a PBH density at reheating of

\[ \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{reh}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{mod}}} \right)_{\text{dec}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{mod}}} \right)_{i} = \alpha_i. \tag{9} \]

Here \( \rho_{\text{rad}} \) and \( \rho_{\text{mod}} \) are the energy densities in radiation and moduli respectively. Therefore, for PBHs formed during moduli domination and surviving beyond it (which is all those of interest), we have

\[ \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{evap}} = \alpha_{\text{evap}} = \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{reh}}}{T_{\text{evap}}}. \tag{10} \]

Considering the duration of the various phases of the evolution of the universe

\[ \frac{t_{\text{evap}}}{t_{\text{Pl}}} = \frac{t_{\text{evap}} t_{\text{dec}} t_i}{t_{\text{reh}} t_{\text{Pl}}}, \tag{11} \]

using the relation between the formation time and mass of a PBH for PBHs formed during radiation domina-
\[ M \cong M_H = \frac{t_i}{t_{Pl}} M_{Pl}, \]  
and the variation of the density during moduli domination, \( \rho \propto t^{-2} \), leads to
\[ \frac{t_{\text{evap}}}{t_{Pl}} = \left( \frac{T_{\text{reh}}}{T_{\text{evap}}} \right)^2 \left( \frac{\rho_i}{\rho_{\text{dec}}} \right)^{1/2} \frac{M}{m_{Pl}}. \]  
In order to eliminate \( \rho_i \), Eq. (7) can be rewritten as
\[ M_H = 0.2 \frac{m_{Pl}^3}{\rho_{\text{dec}}^{1/2}}. \]
Finally the resulting expression for \( t_{\text{evap}} \) can be equated with Eq. (6) to give
\[ T_{\text{reh}} \frac{T_{\text{evap}}}{t_{\text{Pl}}} = 8 \times 10^{-21} \left( \frac{M}{m_{Pl}} \right)^{3/2}, \]
so that
\[ \frac{\beta_i}{1 - \beta_i} = 1 \times 10^{20} \left( \frac{m_{Pl}}{M} \right)^{3/2} \alpha_{\text{evap}}. \]

The gravitational constraints, which require that the present-day densities of PBHs and relics not to overclose the universe, are
\[ \Omega_{\text{PBH, eq}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{eq}} = \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{reh}}}{T_{\text{eq}}} \leq 1 \]  
\[ \Omega_{\text{rel, eq}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{eq}} = \frac{m_{Pl}}{M} \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{reh}}}{T_{\text{eq}}} < 1, \]
where ‘eq’ indicates the epoch of matter–radiation equality in the Universe’s recent past, after which the density of PBHs or relics, relative to the critical density, remains constant. In the case of PBHs with \( M > 2 \times 10^{28} \text{ g} \), formed after moduli domination, the requirement that the present-day density of PBHs does not overclose the universe is obviously the same as in the standard evolution of the universe. The PBHs formed before moduli domination are sufficiently light \( M \leq 10^8 \text{ g} \) that only the relic constraint \( \Omega_{\text{rel, eq}} < 1 \) applies to them, where:
\[ \Omega_{\text{rel, eq}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{eq}} = \frac{m_{Pl}}{M} \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{reh}}}{T_{\text{eq}}} \frac{T_{\text{i}}}{T_{\text{MD}}} < 1, \]  
and in fact it turns out that large initial mass fractions of PBHs, \( \beta_i \sim 1 \), are allowed.

The various limits on the initial mass fraction of PBHs are illustrated in Fig. 2.

\footnote{This equation is not precisely valid for PBHs which are formed during matter domination since their formation may be delayed; however, it can be used in this context since the delay is negligible compared with the PBH lifetime. We will discuss PBH formation during matter domination in more detail later.}

FIG. 2. The tightest limits on the initial mass fraction of PBHs, \( \alpha_i \), if moduli domination commences immediately. The mass is in grams. The rightmost line, indicating the density constraint, continues horizontally until \( M \sim 10^{28} \text{ g} \); PBHs more massive than this form after moduli domination and the standard constraint \( \alpha_i < 10^{-19} \sqrt{M/10^{15} \text{ g}} \) then applies. The constraints are the same as in Fig. 1.

2. **Delayed moduli domination**

An initial value \( \phi \sim m_{Pl} \) is the most natural, but it is not impossible for it to be smaller and this leads to a shorter period of moduli domination. As an example, we take \( \phi \sim 10^{-4}m_{Pl} \) so that moduli domination commences when the energy stored in the oscillations of the moduli field becomes greater than that of the radiation,
\[ \frac{\rho_\phi}{\rho_{\text{rad}}} = \frac{\phi^2}{m_{Pl}^2} \frac{2 \times 10^{13} \text{ GeV}}{T_{\text{MD}}} > 1, \]
at temperature \( T_{\text{MD}} = 2 \times 10^3 \text{ GeV} \).

From Eq. (1), PBHs with \( M < 2 \times 10^{25} \text{ g} \) are formed in the radiation-dominated period before the moduli domination commences. Their energy density, relative to that in other forms, varies as \( T^{-1} \) initially then remains constant during moduli domination. It then increases as \( T^{-1} \) during the subsequent radiation domination so that
\[ \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{evap}} \equiv \alpha_{\text{evap}} = \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{i}}}{T_{\text{MD}}} \frac{T_{\text{reh}}}{T_{\text{evap}}}, \]
leading to
\[ \frac{\beta_i}{1 - \beta_i} = 2 \times 10^5 \frac{m_{Pl}}{M} \alpha_{\text{evap}}. \]

Similarly for the gravitational constraints
\[ \Omega_{\text{PBH, eq}} = \left( \frac{\rho_{\text{PBH}}}{\rho_{\text{rad}}} \right)_{\text{eq}} = \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{i}}}{T_{\text{MD}}} \frac{T_{\text{reh}}}{T_{\text{eq}}} < 1 \]
\[ \Omega_{\text{rel, eq}} = \left( \frac{\rho_{\text{rel}}}{\rho_{\text{rad}}} \right)_{\text{eq}} = \frac{m_{Pl}}{M} \frac{\beta_i}{1 - \beta_i} \frac{T_{\text{i}}}{T_{\text{MD}}} \frac{T_{\text{reh}}}{T_{\text{eq}}} < 1. \]
gravitational collapse is unstable to aspherical growth. The initial perturbation must be sufficiently spherical as to form well within the horizon, but in order to do so because there is no pressure, it is now possible for PBHs to form from rare, relatively large, density fluctuations. The formation rate is given by \(^{19}\)

\[
\beta(M) \approx 2 \times 10^{-2} \sigma^{13/2}(M). 
\]

For PBHs with \(M > 2 \times 10^9\) g, formed during moduli domination, we have

\[
\sigma_{\text{hor}}(M) = \sigma_{\text{hor}}(M_0) \left( \frac{M_{\text{eq}}}{M_0} \right)^{(1-n)/6} \times \left( \frac{M_{\text{dec}}}{M_{\text{eq}}} \right)^{(1-n)/4} \left( \frac{M_0}{M_{\text{dec}}} \right)^{(1-n)/6},
\]

where \(M_0 \simeq 10^{56}\) g is the present horizon mass. PBHs are formed from rare, relatively large, density fluctuations which collapse soon after entering the horizon, so we can take \(M_{\text{hor}} \sim M_0^\dagger\). This simplifies to

\[
\sigma_{\text{hor}}(M) = \sigma_{\text{hor}}(M_0) \left( \frac{M}{M_0} \right)^{(1-n)/6} \left( \frac{M_{\text{dec}}}{M_{\text{eq}}} \right)^{(1-n)/12},
\]

and since during radiation domination \(M_H \propto T^{-2}\)

\[
\sigma_{\text{hor}}(M) = \sigma_{\text{hor}}(M_0) \left( \frac{M}{M_0} \right)^{(1-n)/6} \left( \frac{T_{\text{eq}}}{M_0} \right)^{(1-n)/6} = \sigma_{\text{hor}}(M_0) \left( 1.4 \times 10^{-6} \frac{M}{M_0} \right)^{(1-n)/6},
\]

for masses \(M\) forming during moduli domination.

The lightest holes that can form are determined by the reheating temperature after the original period of inflation which is responsible for generating the density perturbations. The minimum mass is then given by Eq. \(19\). Normally, the tightest constraint on \(n\) comes from the lightest PBHs. We use the method outlined in \(3\), but using the expressions for \(\sigma(M)\) and \(\beta(M)\) given above, to obtain the constraints.

For immediate moduli domination, we find the tightest limit to be \(n < 1.23\) from the deuterium constraint evaluated at \(M \sim 10^{10}\) g, although all the constraints due to the evaporation of PBHs require \(n < 1.32\). The limit from the present-day density of PBHs is tightest at \(M \sim 5 \times 10^{14}\) g giving \(n < 1.30\). Relics do not constrain \(n\), since even very large initial PBH abundances \(\beta_i\) will be diluted away.

For our example case of delayed moduli domination, the most constraining PBHs are formed during the radiation-dominated era before moduli domination commences. For them \(\sigma(M)\) has a different form

\[\]
which simplifies to

$$\sigma_{\text{hor}}(M) = \sigma_{\text{hor}}(M_0) \left( \frac{M_{\text{eq}}}{M_0} \right)^{(1-n)/6} \left( \frac{M_{\text{dec}}}{M_{\text{eq}}} \right)^{(1-n)/4} \times \left( \frac{M_{\text{MD}}}{M_{\text{dec}}} \right)^{(1-n)/6} \left( \frac{M}{M_{\text{MD}}} \right)^{(1-n)/4}, \quad (29)$$

which simplifies to

$$\sigma_{\text{hor}}(M) = \sigma_{\text{hor}}(M_0) \left( \frac{10^5 M}{M_0} \right)^{(1-n)/4}, \quad (30)$$

for our specific parameters. Since the PBHs of interest are formed during radiation domination the standard expression for $\beta$ applies $\beta$ $\approx \sigma(M) \exp \left( -\frac{1}{18\sigma^2(M)} \right). \quad (31)$

The tightest limit is now $n < 1.26$ from the deuterium constraint evaluated at $M \sim 10^{10}$ g, with all the constraints due to the evaporation of PBHs require $n < 1.28$. The tightest limit from the present-day density of PBHs is $n < 1.30$ at $M \sim 5 \times 10^{14}$ g. The relic constraint may provide an even tighter limit if the reheat temperature after inflation is close to $10^{16}$ GeV.

In Fig. 4 we illustrate the variation of $\sigma_{\text{hor}}(M)$ in the standard cosmology, for immediate moduli domination and for our example case of delayed moduli domination.

The tightest constraint for immediate moduli domination is only slightly weaker than in the standard cosmology $\beta$, where the tightest constraint (again deuterium) is $n < 1.22$, with the evaporation constraints all giving $n < 1.24$. There, the relic constraint may give an even tighter limit if the reheat temperature after inflation is high enough ($\sim 10^{14}$ GeV) to let quite light PBHs form. The weakening is only small, since during matter domination PBHs form more readily so that to attain any particular value of $\beta$, a smaller value of $\sigma(M)$, and hence $n$, is necessary. This reduces the effect of the larger value of $\beta$ allowed due to the period of matter domination, and also leads to a larger spread in the limits on $n$ from different sources. The tightest constraint is significantly weaker for delayed moduli domination, since in this case the most constraining PBHs are formed during radiation domination so that the main difference from the standard scenario is the larger values of $\beta$ allowed.

IV. CONCLUSIONS

If there is a prolonged period of matter-domination by moduli in the early Universe, it leads to a weakening of the constraint on density perturbations from primordial black hole formation. It again reminds us of the sensitivity of this bound to the entire assumed cosmological history. If the moduli dominate immediately, the fraction of the density of the Universe permitted to go into PBHs becomes of order $10^{-6}$, rather than the $10^{-20}$ or so which the standard cosmology requires. Delayed moduli domination leads to an intermediate constraint on those PBHs which form before moduli domination. This weakening is similar to that found $\beta$ for the case where an extra period of inflation at low energies, known as thermal inflation, is assumed.

When expressed as a limit on the spectral index of a power-law density perturbation spectrum, we obtain $n \lesssim 1.3$ for immediate moduli domination, rather than $n \lesssim 1.25$ as in the standard cosmology. The weakening is similar to that from thermal inflation, which also led to $n \lesssim 1.3$. Interestingly, the constraint can actually be weakest if moduli domination is delayed, because PBH formation is harder during radiation domination than moduli domination.

We end by noting that the assumption of gaussian perturbations in the black hole formation calculation has recently been questioned by Bullock and Primack $\beta$. As shown in Ref. $\beta$, in the most non-gaussian case found by Bullock and Primack the constraint on $n$ can be weakened further, by up to 0.05.
