Background: Cardiac resynchronization therapy (CRT) is less effective in patients with mildly wide QRS or non-left bundle branch block (non-LBBB). A new algorithm of every minute’s optimization (adaptive CRT: aCRT algorithm) is effective in patients with CRT devices. This study investigated the clinical effect of the aCRT algorithm, especially in mildly wide QRS (120 ≤ QRS < 150 ms) or non-LBBB patients receiving CRT.

Methods and Results: This study included 104 CRT patients (48 patients using the aCRT algorithm [adaptive group] and 56 patients not using the aCRT algorithm [non-adaptive group]). The primary endpoint was a composite clinical outcome of cardiac death and/or heart failure (HF) hospitalization. During a median follow-up of 700 days (interquartile range 362–1,173 days), aCRT reduced the risk of the clinical outcome, even in patients with mildly wide QRS or non-LBBB (log-rank P = 0.0030 and P = 0.0077, respectively) by Kaplan-Meier analysis. Use of the aCRT algorithm was an independent predictor of clinical outcomes in the multivariate analysis (hazard ratio (HR) 0.28, 95% confidence interval (CI): 0.096–0.78, P = 0.015), the same as in patients with mildly wide QRS (HR 0.12, 95% CI: 0.006–0.69, P = 0.015).

Conclusions: The new aCRT algorithm was useful and significantly reduced the risk of the clinical outcome, even in patients with mildly wide QRS.

Key Words: Adaptive cardiac resynchronization therapy; Algorithms; Heart failure; Mildly wide QRS; Non-left bundle branch block

Cardiac resynchronization therapy (CRT) provides substantial clinical benefit in patients with severe left ventricular (LV) dysfunction and QRS prolongation. Various studies of CRT have demonstrated reductions in mortality and hospitalization; however, up to one-third of patients fail to respond to CRT.1–3 Ischemic cardiomyopathy (ICM), large scar burden, and male sex are reported to be factors in the non-response to CRT, and suboptimal atrioventricular (AV) timing is also reported as a potential reason for suboptimal response.4 In contrast, left bundle branch block (LBBB) morphology and wide QRS are revealed as predictors of response to CRT.

A new algorithm of every minute’s optimization (adaptive CRT: aCRT) provides ambulatory adjustment of pacing configuration (synchronized LV (sLV) pacing or biventricular (BiV) pacing) and continuous pacing timings of AV and interventricular (VV) delays based on periodic automatic evaluation of electrical conduction.5 Right ventricular (RV) sLV pacing is selected when AV conduction is normal; in contrast, BiV pacing is selected when AV conduction is prolonged. A previous study demonstrated that the aCRT algorithm is associated with a significant reduction in 30-day readmission, both after heart failure (HF) and all-cause hospitalization.6 Little is known regarding the clinical impact, including on mortality and HF hospitalization, of the aCRT algorithm, however, especially in mildly wide QRS (120 ≤ QRS ≤ 150 ms) or non-LBBB patients. The purpose of this study was to examine the clinical impact of the aCRT algorithm in patients with

mildly wide QRS (120–150 ms) or non-LBBB morphology.

Methods

Study Population

This study was a retrospective single-center cohort study. We investigated 104 patients with a CRT device (Medtronic Inc., Minneapolis, MN, USA) who underwent implantation between 2014 and 2018. Medtronic devices were implanted in all patients. The details of device type were: 71 patients (adaptive: 30 patients, non-adaptive 41 patients) had a Viva® series; 3 patients (all non-adaptive) had a Protecta® series; 11 patients (adaptive: 9 patients, non-adaptive: 2 patients) had a Claria MRI Quad®; and 16 patients (adaptive: 9 patients, non-adaptive: 7 patients) had an Amplia MRI Quad®. Inclusion criteria for CRT devices were implanted transvenously in the standard fashion after obtaining written informed consent from all patients or their guardians. An RV lead was positioned at the RV septal apex, and then the LV lead was implanted in a suitable lateral, posterolateral, or anterolateral branch of the coronary vein at a site that produced an acceptable pacing threshold without diaphragmatic pacing. The aCRT algorithm was programmed from the day of implantation.

The details of the aCRT algorithm have been published previously. In brief, if the conduction interval from the right atrium to the RV is normal (intrinsic AV interval ≤220 ms, if in sinus rhythm or AV interval ≤270 ms, if receiving atrial pacing) and the heart rate does not exceed 100 beats/min, the algorithm provides BiV. The timing of LV pacing is programmed as 70% of the intrinsic atrial pacing to the RVs interval.

The algorithm switches to BiV pacing with an AV delay calculated from the intrinsic intervals between atrial sensing and RVs (A-RVs) and between atrial sensing and RVs interval (A-RV) ≤70 ms. In the non-adaptive group, echo-cardiographic optimization was performed with initial AV delay optimization based on patient transmural flow patterns. Next, VV delay adjustment to produce the greatest aortic velocity time integral was carried out by the iterative method. Two patients in the adaptive group, but none in the non-adaptive group, had a Protecta® series; 3 patients (all non-adaptive) had a Viva® series; 3 patients (all non-adaptive) had a Consulta CRT-P®; 11 patients (adaptive: 9 patients, non-adaptive: 2 patients) had a Claria MRI Quad®; and 16 patients (adaptive: 9 patients, non-adaptive: 7 patients) had an Amplia MRI Quad®. Inclusion criteria for CRT were based on the Japanese guideline, and all patients had QRS width ≥120 ms and LV ejection fraction (LVEF) ≥35%. The adaptive group consisted of 48 consecutive CRT patients using the aCRT algorithm. The non-adaptive group consisted of 56 consecutive CRT patients not using the aCRT algorithm during the same time period. Whether or not the aCRT algorithm was used depended on the physician who implanted the device. Patients with permanent atrial fibrillation (AF), a LV assist device, acute cardiac failure, recent myocardial infarction, coronary artery bypass graft surgery within 3 months, or severe aortic stenosis were excluded. This study was approved by the Institutional Research Board of the National Cerebral and Cardiovascular Center, Suita, Japan (M26-150-7).

Table 1. Comparison of the Characteristics of Patients in the Adaptive CRT ON Group (Adaptive) and the Adaptive CRT OFF Group (Non-Adaptive)

IVCD, intraventricular conduction disturbance; RBBB, right bundle branch block. Other abbreviations as in Table 1.
was defined as intrinsic QRS duration ≥120 ms with a broad notched or slurred R wave in leads I, V5, and V6, and occasional RS pattern in V5 and V6. In addition, Q waves were absent in leads I, V5, and V6, and R peak time was >60 ms in leads V5 and V6 but normal in leads V1–3.12 The widest QRS duration on each 12-lead ECG was manually measured by an expert cardiologist, who was blinded to the patient’s data. Mildly wide QRS was defined as a QRS duration between 120 and 150 ms. Echocardiographic data were collected before and at least 6 months after CRT implantation. A CRT responder was defined as a patient with an improvement in LVEF ≥10% and/or a reduction in LV end-systolic volume (LVESV) ≥15% compared with baseline at 6 months after CRT device implantation, which was the same as the definition of a positive CRT response.13,14 We also evaluated the incidence of cardiac death and HF hospitalization.

Clinical Data
Clinical data were collected for all patients, including age, sex, underlying heart disease, history of AF, medications, echocardiographic data such as LVEF, ratio of mitral peak velocity in early diastole to peak flow velocity in late diastole (E/A), deceleration time (DcT), and ECG data such as QRS morphology, QRS duration, and PQ interval. LBBB of the patients in non-adaptive group, used multipoint pacing. There were no differences in the parameters of ventricular arrhythmia (VA) detection. Among the patients for secondary prevention, we programmed ventricular tachycardia (VT), fast VT, and the ventricular fibrillation detection zone according to the cycle length of the VA. We used a long detection interval (e.g., 30/40 number of internal detections) and a high detection rate (e.g., fast VT ≥182 beats/min), especially in patients for primary prevention.

Figure 1. Study flow chart. aCRT, adaptive cardiac resynchronization therapy.

Figure 2. Kaplan-Meier analyses of freedom from heart failure (HF) hospitalization and/or cardiac death during the follow-up period among all patients. Patients in the adaptive group had a significantly lower risk of cardiac death and/or HF hospitalization than those in the non-adaptive group.
Ueda N et al. (43%) patients were prescribed amiodarone. Mean LVEF was 25±9%. As for comparisons between the adaptive and non-adaptive groups, there were no significant differences in age, sex, indication for defibrillator, and medications. Regarding the ECG parameters, the mean PQ interval was <200 ms in both groups. A total of 24 (50%) patients in the adaptive group and 18 (32%) in the non-adaptive group had a mildly wide QRS and 17 (35%) patients in the adaptive group and 26 (46%) patients in the non-adaptive group had non-LBBB and without RV pacing (Figure 1). In addition, there was no significant difference in the prevalence of responders (P=0.42) (Table 1). In the 42 patients with a mildly wide QRS, there were no significant differences in clinical characteristics except for age (Table 2). Among patients with non-LBBB morphology only, the proportion of intraventricular conduction delay (IVCD) as QRS morphology was significantly higher in the adaptive group than in the non-adaptive group. In addition, the QRS duration was significantly narrower in the adaptive group compared with the non-adaptive group (Table 3).

Results

Clinical Characteristics

Patients’ clinical characteristics are shown in Tables 1–3. Among 104 patients, 74 (71%) were male. Patients were 62±14 years old. In terms of the etiology of underlying heart disease, 18 (17%) patients with ICM and 86 (83%) with non-ICM were included. With respect to medications, 96 patients (92%) were prescribed beta-blockers and 45 (43%) patients were prescribed amiodarone. Mean LVEF was 25±9%. As for comparisons between the adaptive and non-adaptive groups, there were no significant differences in age, sex, indication for defibrillator, and medications. Regarding the ECG parameters, the mean PQ interval was <200 ms in both groups. A total of 24 (50%) patients in the adaptive group and 18 (32%) in the non-adaptive group had a mildly wide QRS and 17 (35%) patients in the adaptive group and 26 (46%) patients in the non-adaptive group had non-LBBB and without RV pacing (Figure 1). In addition, there was no significant difference in the prevalence of responders (P=0.42) (Table 1). In the 42 patients with a mildly wide QRS, there were no significant differences in clinical characteristics except for age (Table 2). Among patients with non-LBBB morphology only, the proportion of intraventricular conduction delay (IVCD) as QRS morphology was significantly higher in the adaptive group than in the non-adaptive group. In addition, the QRS duration was significantly narrower in the adaptive group compared with the non-adaptive group (Table 3).
Clinical Outcome
During a median 700 days (interquartile range 362–1,173 days) of follow-up, 20 patients (adaptive group: 4 patients, non-adaptive group: 16 patients) died of cardiac death, 28 (adaptive group: 8 patients, non-adaptive group: 20 patients) experienced HF hospitalization, and 4 patients (adaptive group: 2 patients, non-adaptive group: 2 patients) had an appropriate shock therapy for VA. The patients in the adaptive group (n=24) showed a significantly lower incidence of either cardiac death or HF hospitalization (log-rank, \(P=0.0030\)) than those in the non-adaptive group (n=18) (log-rank, \(P=0.011\)) as shown in Figure 2. Even in patients with mildly wide QRS duration only, the adaptive group (n=24) showed a significantly lower incidence of cardiac death or HF hospitalization than the non-adaptive group (n=18) (log-rank, \(P=0.0030\), Figure 3A). Among the patients with non-LBBB morphology only, the adaptive group (n=17) also showed a significantly lower incidence of cardiac death or HF hospitalization compared with the non-adaptive group (n=26) (P=0.0077, Figure 3B).

Univariate and multivariate analyses revealed that use of the aCRT algorithm was an independent predictor of cardiac death or HF hospitalization (hazard ratio (HR) 0.28, 95% confidence interval (CI): 0.096–0.78, \(P=0.015\)) (Table 4), the same as in patients with a mildly wide QRS (HR 0.12, 95% CI: 0.066–0.69, \(P=0.015\)) (Table 5).

Discussion
Main Findings
To the best of our knowledge, this is the first study to evaluate the efficacy of the aCRT algorithm for CRT patients with a mildly wide QRS or non-LBBB morphology. This study demonstrated that the aCRT algorithm was associated with a reduction in cardiac deaths and HF hospitalizations of CRT patients, even those with a mildly wide QRS.

Efficacy of the aCRT Algorithm
The aCRT algorithm has been reported to be beneficial and safe in some studies. The aCRT trial showed that the aCRT algorithm resulted in a 44% absolute reduction in the percentage of RV pacing, and the optimization provided by the aCRT algorithm was non-inferior to echocardiographic optimization with respect to clinical, structural, and functional improvements, such as LVESV index, LVEF, New York Heart Association, 6-min walk distance, and Minnesota Living With Heart Failure quality of life. In fact, the proportion of improved clinical composite score of the aCRT group was non-inferior to the echocardiographic optimization group. Starling et al evaluated patients who had ≥1 index hospitalizations during the follow-up in the aCRT trial. They showed that use of the aCRT algorithm was associated with a significant reduction in the probability of a 30-day readmission, both after HF and all-cause hospitalization. In the aCRT trial, however, there were no significant differences with respect to HF events or VA episodes during the follow-up period. Few studies showed a reduction in HF hospitalization or all-cause mortality. Our cohort data revealed that use of the aCRT algorithm was an independent predictor of cardiac death or HF hospitalization, not only in all study subjects (n=104) but also in patients with a mildly wide QRS only.

Possible Mechanism of Effectiveness of the aCRT Algorithm
The aCRT algorithm can provide RV-sLV pacing and adjust the AV and VV delays based on periodic automatic evaluation of electrical conduction. The reduction in RV pacing by the aCRT algorithm may avoid the deleterious effect of iatrogenic ventricular dyssynchrony. Appropriately timed LV pacing was reported to be superior to simultaneous BiV pacing in a CRT subpopulation with sinus rhythm and intact AV conduction. Thus, in patients with normal AV conduction, the aCRT algorithm could be effective.

In addition, optimal AV delay is reported to change dynamically. O’Donnell et al reported a trend towards an increase in the optimal AV delay for CRT during follow-up. Moreover, during exercise, AV delay reduces dramatically and, in this situation, rate-adaptive AV delay

optimization improves LV filling time. Therefore, periodic optimization of the AV delay is essential to enhance the effect of CRT, and the aCRT algorithm may be effective because of its periodic automatic evaluation function.

**aCRT and Mildly Wide QRS or Non-LBBB**

Although CRT is less effective for patients with non-LBBB or mildly wide QRS morphology, the aCRT algorithm reduced the risk of cardiac death and HF hospitalization in our data. Regarding patients with a mildly wide QRS, a previous report, which was a subanalysis of the aCRT trial, showed that the aCRT algorithm could reduce unnecessary RV pacing, preserves the positive net effect of CRT and results in better clinical outcomes for patients who are supposed to respond to CRT, so there was no significant difference in the combined endpoint between the 2 groups. In patients with LBBB, the beneficial effect of CRT may be promised, even with comprehensive echocardiographic optimization, if we can deliver a LV lead to an appropriate site.

In this study, there were significant differences in the prevalence of IVCD and the degree of QRS width among patients with non-LBBB morphology. A high prevalence of complete right bundle branch block (CRBBB) in the non-adaptive group might relate to the inferior effect of CRT compared with the adaptive group, because previous studies have shown that the response to CRT in patients with CRBBB is inferior to those with IVCD. However, our data indicated no significant differences in cardiac death or HF hospitalization between the patients with RBBB and those with IVCD, both in the adaptive and the non-adaptive group. As for QRS width, generally, CRT is beneficial for patients with a wide QRS because it indicates the presence of electrical dyssynchrony. Among patients with limited non-LBBB, the non-adaptive group had a wider QRS duration; therefore CRT was thought to be more beneficial for them. However, the clinical benefits of CRT were significantly higher in the adaptive group compared with the non-adaptive group. We supposed that the aCRT algorithm, which provides periodic optimization of AV and VV delay, was able to preserve appropriate pacing timing continuously in addition to reducing RV pacing, which impairs the physiological activation pattern, generating more electrical dyssynchrony.

**Clinical Implications**

Although CRT is essential therapy for HF patients with prolonged QRS duration, some patients do not respond to it, especially those with a mildly wide QRS or non-LBBB morphology. There were no severe complications related

to use of the aCRT algorithm, such as significant battery consumption or induction of VAs. The aCRT algorithm may be an important tool in the management of patients with a mildly wide QRS or non-LBBB morphology.

**Study Limitations**
This was a single-center retrospective study, so the relatively small number of patients represents the main limitation. Compared with previous studies, the prevalence of ICM patients was relatively small, and as for baseline characteristics of patients with non-LBBB, there were significant differences in the prevalence of IVCD and degree of QRS width between the adaptive and non-adaptive groups. Nevertheless, no previous studies have evaluated the efficacy of the aCRT algorithm for patients with a mildly wide QRS or non-LBBB. Further, prospective multicenter studies including a larger number of patients with CRT devices using the aCRT algorithm are warranted to confirm these findings.

**Conclusions**
The new aCRT algorithm significantly reduced the risk of death and/or HF hospitalization, even in patients with a mildly wide QRS.
